

**Characterization of the novel negative checkpoint regulator
V-domain immunoglobulin-containing suppressor of T-cell
activation (VISTA) on Antigen Presenting Cells**

Von der Fakultät für Medizin und Gesundheitswissenschaften

Summary

Negative checkpoint regulators are targets in immunotherapy directed against the immunosuppressive environment of tumor cells. A novel promising target for checkpoint therapy is V-domain immunoglobulin (Ig)-containing suppressor of T-cell activation (VISTA). VISTA is expressed on the surface of T-lymphocytes, Antigen Presenting Cells (APCs) and cells of tumor tissue. I characterized the role of VISTA on APCs and investigated its intracellular distribution. In addition, I investigated the effect of immunogenic stimulation on the intracellular distribution and the functional effects of VISTA overexpression on APCs.

As professional APCs, I analyzed the expression and localization of VISTA in murine bone marrow derived macrophages (BMDMs) and human monocyte derived macrophages, using immunohistochemistry. Furthermore, I compared my results with the expression of VISTA in the human T-cell line Jurkat and confirmed them by transfecting the myeloid cell lines HL-60 and THP-1 with a VISTA-GFP fusion protein, allowing tracking of VISTA localization. I isolated different cell fractions and organelles of different cell types and analyzed them for the presence of the VISTA. VISTA colocalized in all tested primary cells and cell lines with several vesicle markers along microtubule fibers. Furthermore, I found VISTA expression in the nuclei and secreted exosomes in all tested cells.

Immunogenic LPS activation led to a release of VISTA vesicles to the cell surface in the particle analysis and increased the nuclear VISTA expression in IHC staining for a specific duration. In similarity to VISTA, the model NCR CTLA-4 is stored in vesicles to enable a fast and dynamic adaptation of the surface expression in reaction to immunogenic stimuli. VISTA shows a high homology to the model checkpoint regulator ligand PD-L1, which is expressed in the nucleus as well with an anti-apoptotic function. I conclude that storage of VISTA in vesicles in antigen presenting cells and T-cells allows a fast reaction on immunogenic stimuli. VISTA secretion in exosomes could have a messenger function for cell-cell communication and the nuclear VISTA implies an unknown transcriptional role with an optional positive feedback mechanism or antiapoptotic function.

The overexpression of VISTA-GFP in the myeloid cell lines HL-60 and THP-1 led to increased adhesion and differentiation of the cells towards macrophages. Both cell lines can be differentiated into macrophage-like cells which showed an increased phagocytosis activity with VISTA overexpression. Furthermore, the phagocytosis of human monocyte derived macrophages was increased when engulfing VISTA overexpressing tumor cell lines.

Despite the increased phagocytosis, VISTA is an immunoinhibitory regulator. This is possible via decreased antigen presentation due to VISTA. VISTA overexpression led to a decrease of MHC-II expression. In addition, our collaboration partner discovered via pull out that VISTA and MHC-II are interaction partners. This is an interesting new immunoregulatory axis and target for immunotherapy. The binding of MHC-II as an immunoinhibitory strategy is already known by the immune regulator LAG-3 and could be a promising approach to overcome PD-1 therapy resistance.

VISTA has a complex function and expression pattern on APCs and is able to affect adhesion, differentiation, phagocytosis and the immune function of APCs.

Our results provided new and complementing properties of VISTA and expanded its interaction network. With further investigation of the interaction partners and signaling pathways of VISTA, an efficient and safe VISTA therapy might be possible. Especially a combinational therapy of VISTA with PD-1 or PD-L1 could be able to solve some of the occurring resistance and response rate issues.

Zusammenfassung

Negative Kontrollpunkt Regulatoren (NCR) sind Ziele der Immuntherapie, die sich gegen die immunsuppressive Umgebung von Tumorzellen richtet. Ein neuer vielversprechender Angriffspunkt dieser Kontrollpunkt-Therapie ist V-domain immunoglobulin (Ig)-containing suppressor of T-cell activation (VISTA). VISTA ist auf der Oberfläche von T-Lymphozyten, Antigenpräsentierenden Zellen (APCs) und Tumorgewebe exprimiert. Ich habe die Rolle von VISTA auf APCs und seine intrazelluläre Verteilung charakterisiert und untersucht. Dabei habe ich den Effekt immunogener Stimulation auf die intrazelluläre VISTA Verteilung und die funktionalen Auswirkungen für APCs mit VISTA Überexpression, untersucht.

Dazu habe ich in professionellen APCs per Immunohistochemie (IHC) die Expression und Lokalisation von VISTA in murinen Makrophagen aus Knochenmark (BMDMs) und humanen Makrophagen aus Monozyten analysiert. Meine Ergebnisse habe ich mit der VISTA Expression in der humanen T-Zelllinie Jurkat verglichen und durch die Transfektion der myeloiden Zelllinien HL-60 und THP-1 mit einem VISTA-GFP fluoreszierenden Fusionsprotein, das die Verfolgung der VISTA Lokalisation ermöglicht, bestätigt. Ich habe diverse Zellfraktionen und Organellen verschiedener Zelltypen isoliert und auf die Präsenz von VISTA hin untersucht. VISTA kolokalisierte in allen getesteten primären Zellen, sowie Zelllinien entlang von Mikrotubulin Fibern mit mehreren Vesikelmakern. Außerdem habe ich für alle getesteten Zellen, VISTA Expression im Zellkern und in sekretierten Exosomen gefunden.

Die immunogene Aktivierung mit LPS führte laut unserer Partikelanalyse zu einer Freisetzung der VISTA Vesikel an die Zelloberfläche und erhöhte die nukleare VISTA Expression für eine gewisse Dauer in IHC Färbungen. Wie VISTA, wird auch der Modell NCR CTLA-4 in Vesikeln gelagert, die eine schnelle und dynamische Anpassung der Oberflächenexpression an immunogene Stimuli erlauben. VISTA zeigt eine hohe Homologie zu dem Modell Kontrollpunkt Regulator Liganden PD-L1, der auch im Kern exprimiert wird, mit anti-apoptotischer Funktion. Ich komme daher zu dem Schluss, dass das Lagern von VISTA in Vesikeln in Antigenpräsentierenden Zellen und T-Zellen eine schnelle Reaktion auf immunogene Stimuli ermöglicht. Die VISTA Sekretion in Exosomen könnte eine Botenstoff Funktion für die Zell-Zell-Kommunikation ermöglichen und die nukleare Expression von VISTA impliziert eine bisher unbekannte transkriptionale Rolle von VISTA mit optionalem positiven Rückkopplungsmechanismus oder anti-apoptotischer Funktion.

Die Überexpression von VISTA-GFP in den myeloiden Zelllinien HL-60 und THP-1 führte zu erhöhter Adhäsion und Makrophagen Differenzierung der Zellen. Beide Zelllinien können in Makrophagen-ähnliche Zellen differenziert werden, die nach VISTA Überexpression eine erhöhte Phagozytose Aktivität zeigten. Auch die Phagozytose von humanen Makrophagen aus Monozyten war erhöht, wenn sie Tumorzelllinien mit VISTA Überexpression phagozytierten.

Trotz der erhöhten Phagozytose, ist VISTA ein immuninhibierender Regulator. Das ist möglich indem VISTA die Antigen Präsentation senkt. Überexpression von VISTA führte zu einer geringeren MHC-II Expression. Außerdem haben unsere Kooperationspartner durch einen Pull-out Assay herausgefunden, dass VISTA und

MHC-II Interaktionspartner sind. Dies stellt eine neue interessante immunregulatorische Achse dar, die als Ziel der Immuntherapie dienen könnte. Die Strategie MHC-II als immuninhibitorische Strategie zu binden, ist bereits von dem Immunregulator LAG-3 bekannt und könnte einen vielversprechenden Ansatz darstellen, um zukünftig die Resistenz gegen PD-1 Therapie zu überwinden.

VISTA hat eine komplexe Funktion und Expressionsmuster auf APCs und ist damit in der Lage die Adhäsion, Differenzierung, Phagozytose und Immunfunktion von APCs zu beeinflussen.

Unsere Ergebnisse zeigten neue und ergänzende Eigenschaften von VISTA und haben das bisher bekannte Interaktionsnetzwerk von VISTA erweitert. Mit weiteren Untersuchungen der Interaktionspartner und Signalwege von VISTA, könnte zukünftig eine effiziente und sichere VISTA Therapie möglich sein. Insbesondere die kombinierte Therapie von VISTA und PD-1 oder PD-L1 könnte in der Lage sein, die bestehenden Schwierigkeiten von Therapie Resistenz und geringen Ansprechraten zu lösen.

1 Introduction

1.1 Immune system

Our body uses two defense systems against infections and pathogens: the innate and the adaptive immune system.

The innate immune system reacts rapidly to structures which are common on many pathogens. It recognizes structure elements like specific glycolipids or nucleic acid formations, which are highly conserved between many pathogens but absent in humans. The innate immune system is maintained by phagocytes like macrophages, dendritic cells and neutrophils, but also by mast cell, basophils, eosinophils and natural killer cells. These immune cells phagocytose and kill the pathogens, which they identified by the conserved structure elements.

But the repertoire of this fast innate system is limited and not able to adapt to new structures on pathogens. So, a more organized system with the ability of adaptation and evolution is needed in addition.

The adaptive immune system reacts on pathogen specific peptides and proteins called antigens. It can build 10^8 different antibodies and more than 10^{12} T-cell receptors (TCRs) which represent different surfaces. It is slower than the innate system but has the ability of evolutionary adaptations and a memory function of experienced pathogens.

The adaptive immune system can be distributed in humoral and the cellular immunity. In the humoral immunity, soluble proteins, called antibodies or immunoglobulins, bind foreign antigen molecules, marking pathogens on the surface for destruction. These antibodies are produced by B-cells.

In the cellular immune response cytotoxic T-lymphocytes kill infected cells. Intracellular infections are not visible on the cell surface, so vertebrates developed a mechanism to mark the cell surface with molecules from the cell and from the foreign content. Some of the internal proteins are degraded to peptides and bind to major histocompatibility complex-I or -II (MHC-I/-II) as antigens. T-cells check the complexes with their T-cell Receptors (TCRs) to find and kill infected cells.

In addition, Antigen Presenting Cells (APCs) like dendritic cells of the innate immune system, phagocytose pathogens and present their proteins as antigens to naive T-cells in the lymphatic system on MHC-II complexes. That leads to an efficient combination of the innate and the adaptive immune system against pathogens.

But the binding of TCR to MHC-II on APCs is not sufficient for a T-cell activation. It needs a second costimulatory signal by CD28, a B7 costimulatory receptor, binding CD80/86 on the Antigen Presenting Cell surface for a sufficient activation signal (Figure 1.1.1). When both signals are combined, the T-cell grows, proliferates and differentiates to a cytotoxic T-cell. The cytotoxic T-cell kills its target cells by releasing cytokines and direct killing (Berg et al. 2011).

The combination of different costimulatory and coinhibitory receptors on the APCs and T-cells define the magnitude and duration of the T-cell activation (Khoja et al. 2015). A variety of immunomodulatory signals are needed to orchestrate the antigen-specific immune response (Callahan and Wolchok 2013).

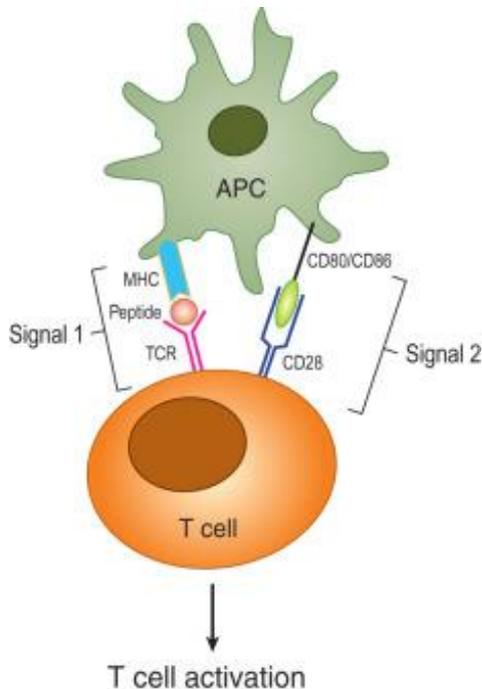

Figure 1.1.1: The two signals of T-cell activation via TCR and CD28 by Antigen Presenting Cells (Rich 2019)

1.2 Anti-tumor immune responses and immunotherapy

A cancer cell is defined as a cell which lost its normal regulatory processes, leading to uncontrolled cell growth and formation of metastases (Hanahan und Weinberg 2011). The metastatic diseases are responsible for 90 % of cancer deaths (W. et al. 2014). Aberrant proteins, also called oncoproteins, regulate several biological processes like proliferation, motility, angiogenesis, deoxyribonucleic acid (DNA) repair and metabolism etc., providing the basis for cancer development (Hanahan und Weinberg 2011; Helleday et al. 2008; CHAFFEY 2003). Normally, the immune system is capable to prevent the formation of cancer via the cancer immunity cycle (Chen und Mellman 2013). The cyclic process starts with the release of cancer cell specific antigens from the tumor cells. Antigen Presenting Cells (APCs) take up, process and present the Antigens on MHC-II towards T-lymphocytes in the lymph nodes. Leading to priming and activation of naive T-cells specifically against the tumor cells. The activated cytotoxic T lymphocytes (CTL) infiltrate into the tumor and kill the cancer cells after recognizing the cancer antigen. Dead tumor cells release cancer cell antigens again, leading to a self propagating amplifying cycle (Chen und Mellman 2013).

Therefore, every cancer which was able to develop and grow established a strategy to evade this immune surveillance (Figure 1.2.1). For that, Schreiber and colleagues described the three phases of “cancer immunoediting”:

1. The elimination phase by which innate and adaptive immune response is triggered to specific tumor-associated antigens;
2. The equilibrium phase by which a balance between immune-mediated destruction and persistence of rare mutated malignant cell clones is created, and
3. Immunologic escape by which the malignant cancer clones are able to evade the adaptive immune system and continue growing

(Schreiber et al. 2011)

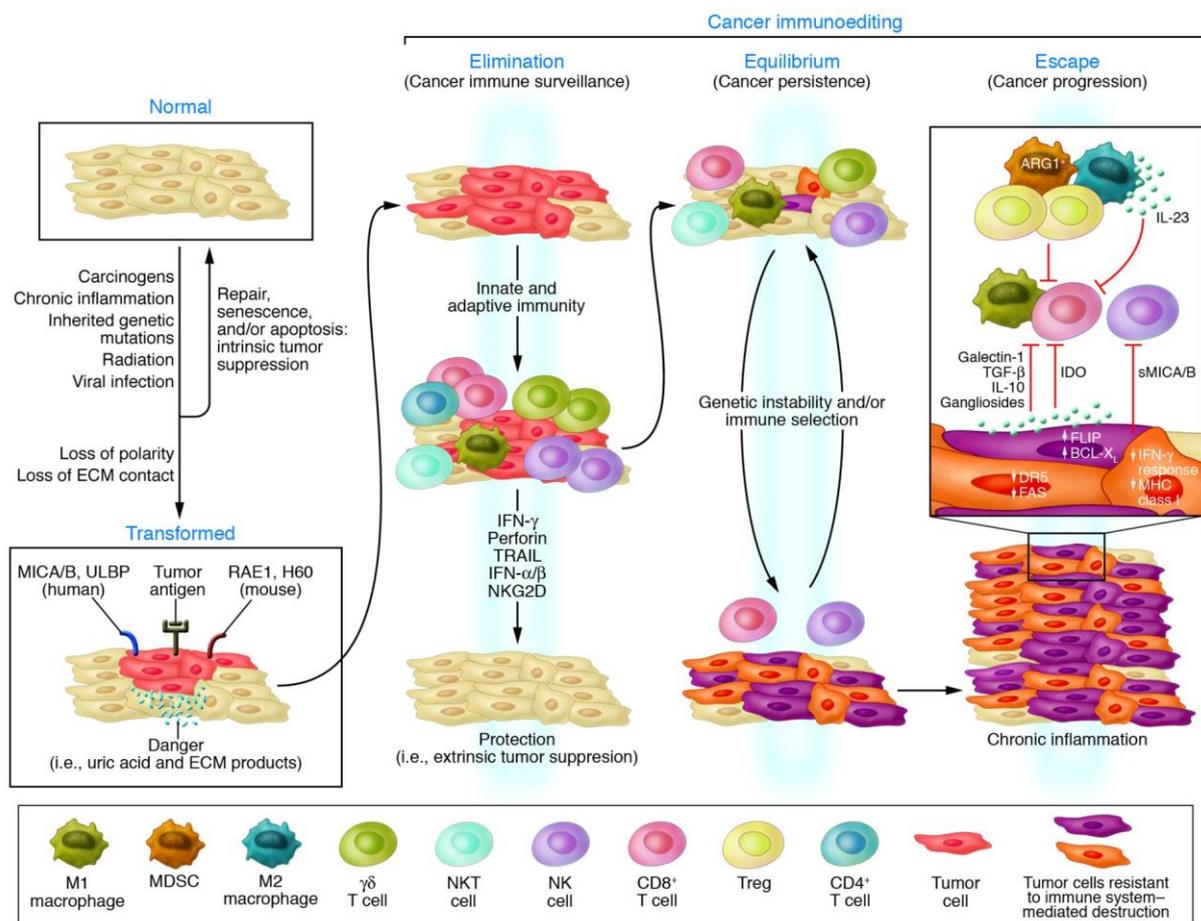

Figure 1.2.1 Cancer immunoediting (Swann und Smyth 2007) of transformed tissue. Distributed in the three phases elimination, equilibrium and escape leading to progressing cancer cells resistant to immune destruction.

This deregulated immune response in cancer, allows tumor cells to escape from the immune surveillance. But tumors can also use other mechanisms to evade the immune surveillance, like loss or alteration of specific neoantigens, promotion of an immune-tolerant microenvironment by manipulation of cytokines and upregulation of immune checkpoint molecules (van Limbergen et al. 2017; Blank et al. 2016).

The immunotherapy was developed to prevent the tumor cells avoiding the immune destruction and hiding from the immune surveillance. For that, immunotherapy stimulates and boosts the patient's immune system to improve or restore the immune system function so it will kill the cancer cells independently. One of the main advantages of boosting the immune system compared to classical cancer therapy with e.g. chemotherapy is that the immune system will also recognize and destroy all distant metastases, when triggered against cancer cells specifically. In addition, the immune system can prevent a relapse of cancer because of the memory function of the adaptive immune system.

There are several types of immunotherapy, including:

- Non-specific immunotherapies
- Cancer vaccines
- Oncolytic virus therapy
- T-cell therapy
- Monoclonal antibodies and tumor-agnostic therapies

1.2.1 Non-specific immunotherapies

In comparison to other immunotherapies the non-specific immunotherapy activates the immune system generally but not via responses against an antigen or a set of antigens. These therapies involve both the innate and adaptive immune system and are often given together with other cancer treatments like chemotherapy or radiation. These therapies include:

- cytokines like interleukins and interferons
- immunostimulatory agents like the Bacille Calmette-Guérin germ
- enzyme inhibitors

They can reverse the immune suppression, act directly on anti-tumor cells, activate the innate immunity or activate T-cells without specific antigen (Monjazeb et al. 2012).

Interleukin 2 for example helps the immune system to produce faster and more T-cells and is used to treat kidney cancer and skin cancer.

All non-specific immunotherapies can lead to flu-like symptoms, weight gain, heart problems and other side effects. In addition, the impact is limited because of the non-specific function.

1.2.2 Cancer vaccines

A cancer vaccine exposes the immune system to a cancer specific antigen. It either treats existing cancer, known as therapeutic cancer vaccines, or prevents development of cancer.

Some tumors caused by viruses, like liver cancer and carcinoma of the uterine cervix, can be prevented by HBV or HPV vaccines (Chang et al. 1997; Wheeler 2007).

For the therapeutic cancer vaccine proteins from cancer cells are separated to immunize patients as antigens and stimulate the immune system against these cancer cells (Giarelli 2007).

Another approach is to vaccinate patients via oncolytic viruses, as described in 1.2.3.

The therapeutic vaccination against established tumors shows disappointing effectiveness. Suboptimal vaccine design and an immunosuppressive tumor microenvironment are discussed as possible reasons. It is difficult to find an antigen which is evaluated as foreign for the immune system and is expressed on the majority of the heterogenous tumor cells. To enhance cancer vaccines, the antigen choice needs to be improved and combinational treatments that reverse immunosuppressive mechanisms, like PD-1 blockade (chapter 1.3.1) are suggested (Yang 2015).

1.2.3 Oncolytic virus therapy

The oncolytic virus therapy uses genetically modified viruses which can replicate in cancer cells, but not in healthy cells, leading to the lysis of tumor cells. Lysis of the cancer cell releases cancer cell antigens, which triggers the patient's immune system into the immunosuppressive environment of tumors. As a result, the immune system will target all the cancer cells with the same antigens. Involving the innate and adaptive immune system, this therapy leads to a long-lasting immunological memory which avoids relapse and metastatic spread (Marelli et al. 2018). The FDA approved the first oncolytic virus therapy, called T-VEC, against melanoma. There are several more constructs in different virus types in development but with unsatisfactory results so far. The main issue of oncolytic viruses is that they are recognized by the immune system as pathogens and could be cleared without a sufficient anti-tumor effect due to anti-viral immunity. Therefore, it is important to design oncolytic viruses that replicate and spread quickly within tumors before viral clearance.

In addition, it is difficult for oncolytic viruses to infect large tumors due to the physical barriers or the poor tumor vascularization.

Oncolytic viruses are mostly administered intravenous which leads to several obstacles and side effects. The main obstacle of this therapy is the clearance of the virus via the host immune system before it has an impact on the target tissue. Oncolytic viruses can also hyper activate the immune system leading to fever, fatigue, nausea and flu-like symptoms. In elderly patients they can cause a chronic infection due to the weaker immune system leading to side effects and a resistance to the therapy.

To use this therapy more widely in the future, it is important to find a balance between the anti-viral response and the anti-tumor response. For that purpose, safer but more powerful viruses are needed. Therefore oncolytic viruses are tested in combination with classical treatments or other immunotherapies (Marelli et al. 2018).

1.2.4 T-cell therapy

For T-cell therapy of cancer, T-cells are removed from the patient's blood (or another healthy donor), genetically engineered to produce an artificial T-cell receptor on their surface and injected back in the patient with improved cancer killing properties.

The therapy based on this principle is called chimeric antigen receptor (CAR) T-cell therapy and can redirect cytotoxic T-cells to cancer cells which express the corresponding tumor cell specific antigen. The receptors are chimeric because they are a combination of antigen-binding and T-cell activating functions in a single receptor.

T-cells engineered with CARs were first described by Zelig Eshhar in 1993. They transduced T-cells with chimeric genes, which encoded for single-chain antibodies linked to a transmembrane region and an intracellular domain encoding the signaling adaptor for the T cell receptor (Eshhar et al. 1993; Yang 2015).

CD19 CAR-transduced human peripheral blood T lymphocytes show impressive clinical outcomes in several lymphoma and leukemia including relapsed or refractory B cell malignancies. Unfortunately, for solid tumors CAR T-cell therapy only shows modest results. It is more difficult to identify antigens in solid tumor, which are present on the majority of cancer cells, but absent in normal tissues. In addition, CAR T-cells failed to enter the center of solid tumors efficiently (Yang 2015).

Due to the difficulty of finding a specific antigen, there are serious side effects after CAR T-cell therapy including cytokine release syndrome (CRS) and neurological toxicity (Hartmann et al. 2017).

Moreover, there are concerns about the long-term survival of CAR T-cells in patients and the effects on pregnancy. CRS in patients is used as a diagnostic marker if the CAR T-cell therapy is effective and occurs in almost all patients. In this condition an increased number of inflammatory cytokines are released, which leads to high fever, cardiac dysfunctions, liver failure, kidney impairment and several other symptoms (Bonifant et al. 2016).

Neurological toxicity is also often associated with CAR T-cell treatment and led to several cases of death or irreversible brain damage (clinicaltrials.gov NCT02535364). The difficulty to find a cancer cell specific antigen can also lead to CAR T-cells attacking non-tumor tissue with different severities of side effects (Makita et al. 2017). Because CAR T-cells were produced by viral vector intertion there is the unlikely possibility that CAR T-cells transform into cancerous cells through intertional mutagenesis.

To overcome these issues there are now Smart T-cells in development including a suicide gene or other synthetic switches to precisely control the timing and dosage of the therapy and to shut off the CAR T-cell therapy when severe side effects occur (Makita et al. 2017).

1.2.5 Monoclonal antibodies and tumor-agnostic therapies

Monoclonal antibodies can be used in different ways of immunotherapy. Monoclonal antibodies can be used like humoral immunity where they attach to specific antigen

proteins on cancer cells and flag the cells for destruction. Other antibodies work by releasing the brakes on the immune system via blocking negative checkpoint regulators, called immune checkpoint therapy which will be introduced further in chapter 1.2. The checkpoints are activated by ligand-receptor interaction and the antibodies are designed to block the interaction between ligands on tumor and their checkpoint receptors on immune cells (Alatrash et al. 2013).

Most immune checkpoint inhibitors are approved for specific cancers, but some are used to treat tumors with a specific genetic change anywhere in the body, so called tumor-agnostic treatments. For example, there are antibodies approved against metastatic or unresectable tumors with a high microsatellite instability or DNA mismatch repair deficiency. These tumors develop often many mutations and are more easy to be identified by the immune system (Khoja et al. 2015; Sundar et al. 2015).

To increase the response rate there are many combinations of different antibodies against negative checkpoint regulators in clinical trials.

Like all immunotherapies the monoclonal antibody therapy can lead to several side effects. All of them are immune-related adverse events like flu-like symptoms, allergic reactions, hepatic toxicity, colitis or autoimmune toxicity. Death cases were observed because of the toxicity of immune-related adverse effects, but in contrast to other oncology treatments, the toxicities do not appear to be cumulative over time (Alatrash et al. 2013; Agarwala 2015).

The biggest issue of the checkpoint therapy so far, is the unprecise prediction which patients will benefit from it. There are currently many studies looking for biomarkers, but beside the ligand expression level of negative checkpoint regulators no biomarkers are identified so far and the ligand expression is not sufficient to predict the therapeutic outcome (Agarwala 2015).

Immune checkpoint therapy and CAR T-cells are the most successful immunotherapies so far and highlight a breakthrough for cancer immunotherapy. However, immunotherapy only works on a subset of cancers, it is struggling especially in treatment of solid tumors, and only a minor subset of patients are responding to immunotherapy (Yang 2015).

After this general introduction about possible immune therapies I will focus on the checkpoint therapy and their targets for this thesis.

1.3 Negative checkpoint regulators and immune checkpoint therapy

Negative checkpoint regulators (NCRs) are molecules that decrease T-cell activation and cell-mediated immune response within a safe range for the host. Many of the NCRs are part of the CD28-B7 protein family. NCRs are the most important brake for tendering the TCR signaling against overreactions of the immune system. Deletion or blocking of NCRs can lead to strong autoimmune reactions or chronic infections.

Negative checkpoint regulators can act as receptors and ligands. In this system the term “receptor” refers to the surface protein on cytotoxic T-lymphocytes (CTLs) while the term “ligand” describes the surface protein on all other cell types that interact with the CTLs. But many NCR receptors and ligands have multiple binding partner and interact bidirectional. This complex signaling must be considered in immunotherapy against negative checkpoints regulators (Lines et al. 2014b).

Prototypical NCRs are CTLA-4 and PD-1 which are now introduced further.

1.3.1 PD-1 and PD-L1

Programmed Death receptor-1 (PD-1) was discovered in 1992 and is a member of the CD28-B7 superfamily. This NCR is expressed on T-cells, B-cells, monocytes, natural killer T-cells and Antigen Presenting Cells (APCs) like Dendritic Cells (DCs), with the highest immunoinhibitory relevance as a receptor on B- and T-cells (Ishida et al. 1992; Nishimura et al. 1999; Nishimura et al. 2001). It binds its ligands PD-L1 and PD-L2 on Antigen Presenting Cells. PD-1 is a critical NCR, which has an immunoregulatory role, tinders inflammation and maintains the peripheral tolerance. Upon immune activation PD-1 is upregulated on T-cells and B cells (Agata et al. 1996). PD-1 expression is upregulated by common γ -chain cytokines and VEGF (Kinter et al. 2008; Voron et al. 2015).

PD-1 modulates the antigen-specific immune response against infection and cancer (Freeman et al. 2000; Iwai et al. 2002; Iwai et al. 2005). The binding of PD-1 with its ligands (Figure 1.3.1.1 b) leads to a decreased cytokine production, cytotoxicity and antibody formation. Therefore, PD-1 inhibits autoimmunity and anti-tumor or anti-infection immunity (Okazaki et al. 2013).

PD-1 suppresses the T-cell function via forming microclusters which associate to the phosphatase SHP-1. The phosphatase dephosphorylates the TCR leading to a suppressed immune reaction (Yokosuka et al. 2012).

Ligands of PD-1

One of the PD-1 ligands, Programmed Death-Ligand 2 (PD-L2) can be induced on dendritic cells (DCs), monocytes and macrophages whereas Programmed Death-Ligand 1 (PD-L1) is expressed broadly and constitutively on immune cells in the whole body and has a greater importance for immune therapy. PD-L1 is a surface glycoprotein which is also called B7-H1 or CD274 (Satelli et al. 2016). Its expression on T-cells, macrophages and tumor cells is inducible by common γ -chain cytokines (IL-2, IL-4, IL-7, IL-15, IFN γ and GM-CSF) and can be increased by type I or II interferons (Yamazaki et al. 2002; Keir et al. 2008; Kinter et al. 2008).

The production of IFN γ by tumor infiltrating lymphocytes (TILs) induces the PD-L1 expression, therefore suppresses the TIL activation and leads to T-cell exhaustion or anergy. A high PD-L1 expression can be induced by TIL infiltration.

Tumors which evaded the immune control also show high PD-L1 expression. In addition, PD-L1 is upregulated by HIF- α in the hypoxic tumor microenvironment (TME)

(Noman et al. 2014). In this case, PD-L1 expression can be used as a biomarker for immune evasion.

Especially PD-L1 in the periphery is important to prevent autoimmune reactions or bystander effects. Therefore, the binding of PD-1 to PD-L1, which tinders the cytotoxic T-cell function, implicates T-cell exhaustion and immune evasion by tumors (Figure 1.3.1.1 b) is most effective in the periphery (Taube et al. 2012; Xu et al. 2018). PD-L1 expression correlates with invasiveness, metastasis and a poor prognosis.

Role of nuclear PD-L1

Beside its expression on the cell surface of immune cells, PD-L1 also shows nuclear expression in some cells. PD-L1 is a membrane protein and therefore its nuclear expression is unexpected. It does not contain any classical nucleus import motif, but shows interaction with nuclear import/export proteins in its interactome (Escors et al. 2018).

In addition to its function of T-cell inhibition, an anti-apoptotic role with molecules in the nucleolus is discussed for nuclear PD-L1. Surface expression is down- and nuclear PD-L1 expression is upregulated due to chemotherapy with Doxorubicin which is one of the most effective Anthracyclines and induces immunogenic apoptosis in tumor cells (Ghebeh et al. 2010). Nuclear PD-L1 was also found in strongly apoptosis resistant circulating tumor cells (Ghebeh et al. 2010; Satelli et al. 2016). Based on nuclear PD-L1 in circulating tumor cells, it was also observed, that nuclear expression of PD-L1 is induced by the lack of cell-cell contact (Satelli et al. 2016). The PI3K/Akt pathway seems to be involved in nuclear upregulation of PD-L1 displayed by increased phosphorylated Akt in the nucleus with nuclear PD-L1 expression.

The nucleus expression seems to enhance the apoptotic resistance which is displayed by chemotherapy resistance and is correlated with a bad prognosis if found in tumor cells (Ghebeh et al. 2010; Satelli et al. 2016; Granier et al. 2017).

Antibody therapy

There are several antibodies against the PD-1/PD-L1 NCR axis developed and in clinical trials, because tumor cells upregulate PD-L1 to inhibit cytotoxic T-cell function and evade the immune system. PD-1/PD-L1 antibodies prevent tumor cells from binding and “turning off” T-cells (Figure 1.3.1.1 c) (Rojas and Casablanca 2019). The expression of PD-L1 on tumor cells and PD-1 on TILs is associated with clinical responses towards antibody-mediated therapy (Nishino et al. 2017). In general, the blocking of PD-1 reverses the exhausted CD8⁺ T-cells and leads to a specific anti-tumor immune reaction (Kondo et al. 2016).

The monoclonal anti-PD-1 antibody Pembrolizumab shows effectiveness in several advanced tumors, especially when they have a mismatch repair deficiency (dMMR) or microsatellite instability (MSI). Pembrolizumab is approved by FDA for women with dMMR or MSI endometrial cancer (Rojas und Casablanca 2019).

In addition, the anti-PD-1 Nivolumab or anti-PD-1+anti-PD-L1 antibody Lambrolizuman are effective against advanced melanoma, non-small-cell lung cancer, prostate cancer, renal cell cancer and colorectal cancer. Patients showing high PD-L1 expression seem

to respond with a higher probability (Topalian et al. 2012; Rojas and Casablanca 2019; Sundar et al. 2015).

Also, anti-PD-L1 antibodies are in clinical trials. One example would be the monoclonal anti-PD-L1 antibody Avelumab in advanced or recurrent endometrial cancer (Rojas and Casablanca 2019).

But there are several side effects and adverse events in patients receiving an anti-PD-1 and/or anti-PD-L1 therapy. General effects are fatigue (16-24 %) and infusion-related reactions (25 %). Additional effects are skin and mucosal manifestations, GI-effect like diarrhea or colitis, hepatotoxicity, pneumonitis and thyroid dysfunction (3,8 – 13,2 %). Whereas Pembrolizumab leads to augmented dermatological complications, Nivolumab causes more often the potentially serious adverse effect of pneumonitis (3 %). The probability for a pneumonitis is small but it can be potentially fatal, so the early identification is crucial (Rojas und Casablanca 2019; Topalian et al. 2012).

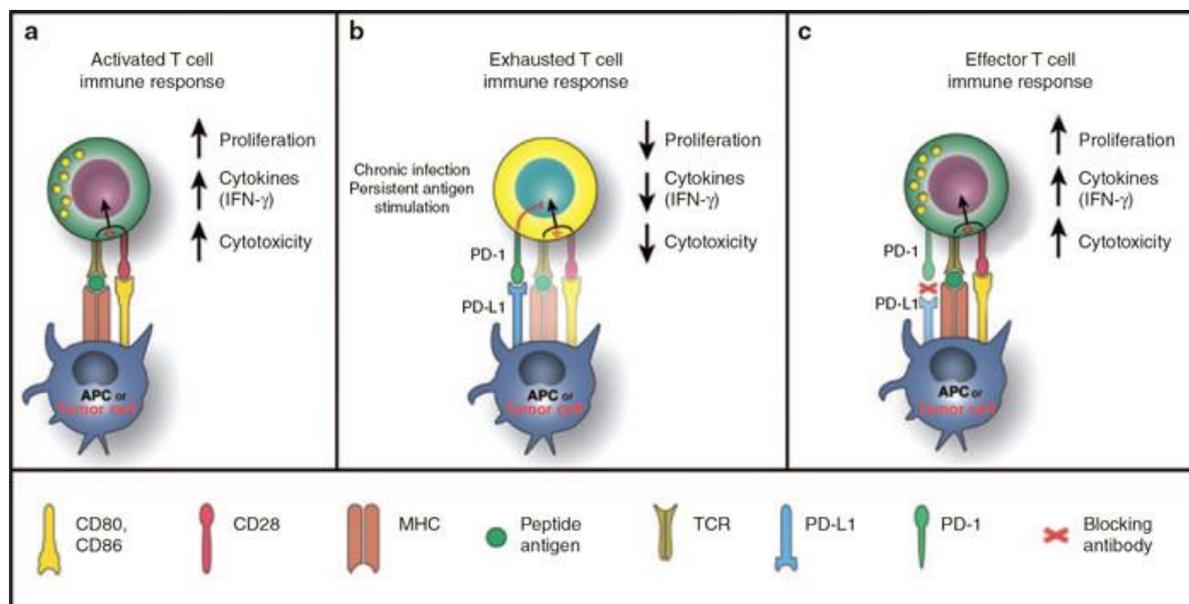

Figure 1.3.1.1: Immunological function of PD-1 and its antibody therapy (Harvey 2014). Distributed in the normal activation of T-cells by APCs (a), the immunoinhibitory effect of PD-1 binding its ligand PD-L1 on the APC or tumor cell surface (b) and the immunostimulatory effect of blocking PD-1 PD-L1 interaction with an antibody (c).

1.3.2 CTLA-4

The T-cell receptor and costimulatory molecule NCR Cytotoxic T-lymphocyte-associated Protein 4 (CTLA-4 or CD152) competes with CD28 for the binding with CD80 (B7-1) and CD86 (B7-2) (Figure 1.3.2.1 A). Like that CTLA-4 tinders the extent of early naive and memory T-cell activation and interrupts the TCR signaling. CTLA-4 has a higher affinity to CD80 and CD86 compared to CD28, so the blocking of the TCR signaling is controlled by surface expression of CTLA-4. The importance of limiting the TCR signal by CTLA-4 can be observed in mice with deleted CTLA-4, which develop a fatal systemic lymphoproliferative disease with multiorgan lymphocytic infiltration and damage within 3-4 weeks of age (Linsley et al. 1996; Wing et al. 2008).

CTLA-4 functions on the cell surface but is mainly stored in intracellular endocytic and secretory vesicles. Activation of T-cells induces an increased mRNA expression of CTLA-4 and a release from intracellular storages which leads to a focused surface expression of CTLA-4 towards the sites of TCR activation (Linsley et al. 1996).

Antibody therapy

Ipilimumab was the first human monoclonal anti-CTLA-4 antibody and started a new era of cancer immunotherapy. It was approved by FDA in 2011 against metastatic melanoma (Figure 1.3.2.1 B) and increased the 1- and 2-year survival from 25 % and 14 % in the controls to 46 % and 24 % (Yang 2015; Alatrash et al. 2013; Ribas 2007; Cameron et al. 2011; Tarhini et al. 2010). It promotes antitumor response by T-cell activation and tumor infiltration. It has been shown to be active in melanoma, prostate cancer and is being studied in gynecologic cancer in combination with nivolumab currently (Rojas and Casablanca 2019). Another antibody developed against CTLA-4 for advanced melanoma patients is Tremelimumab (Kirkwood et al. 2010).

The blocking of CTLA-4 releases the brakes on antitumor T-cell responses and ablates regulatory T-cells (Tregs) within the tumor microenvironment (TME). Therefore, its main therapeutic mechanism is the blockade of Tregs (Kondo et al. 2016; Tarhini et al. 2010).

But the therapeutic use of anti-CTLA-4 antibodies Ipilimumab and Tremelimumab also showed unexpected toxicities like tissue-specific inflammation in a unique distribution of sites (Figure 1.3.2.1 B). The most commonly affected tissues are the skin (rash, pruritus, vitiligo), bowel (diarrhea, colitis), liver (hepatitis, elevated liver enzymes) the pituitary and other endocrine glands (hypophysitis, hypothyroidism, thyroiditis, adrenal insufficiency) (Hodi et al. 2010).

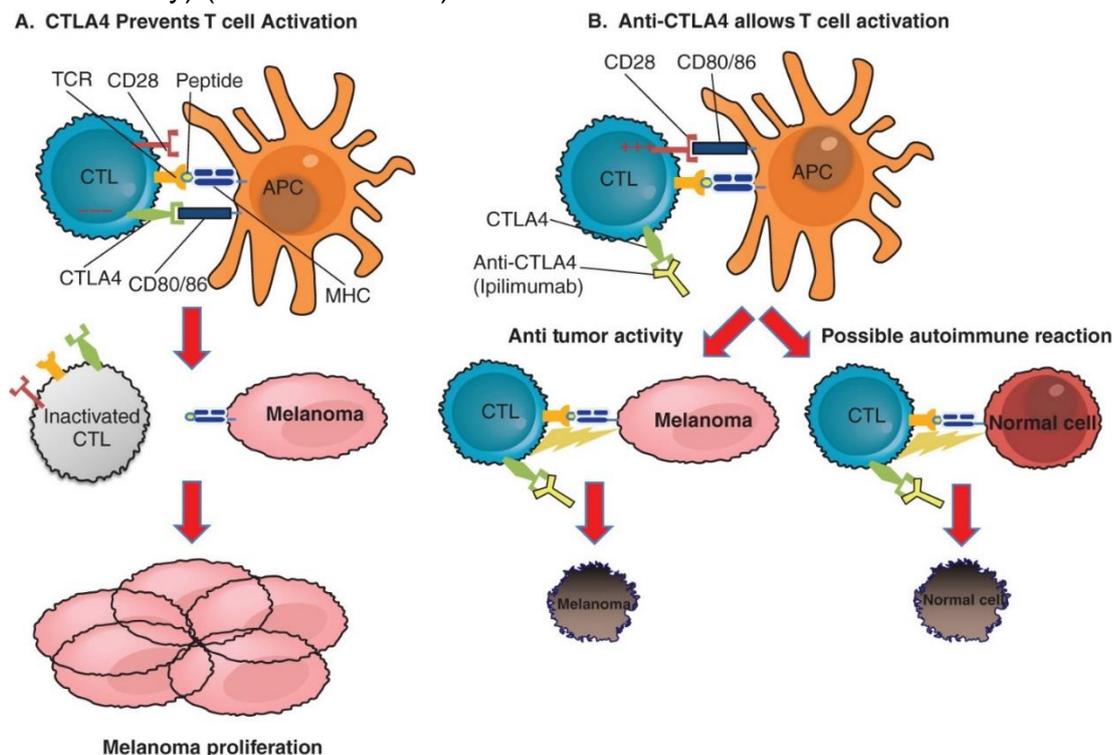

Figure 1.3.2.1: Function of CTLA-4 and anti-CTLA-4 therapy on melanoma (Alatrash et al. 2013). CTLA-1 binds CD80/86, preventing T-cell activation. This leads to inactivated cytotoxic T lymphocytes enabling

melanoma proliferation (A). Blocking of CTLA-4 via antibody enables cytotoxic T lymphocyte activation leading to anti-tumor activity but also possible autoimmune reactions against normal cells (B).

1.3.3 V-domain Ig Suppressor of T-cell Activation (VISTA)

Protein structure and expression on immune cells

V-domain Ig Suppressor of T-cell Activation (VISTA, based on early investigations also known with the following abbreviations: GI24, Dies-1, DD1 α , PD-1H, B7-H5, C10orf54, PP2135, SISP1; gene:Vsir) is a newly discovered negative checkpoint regulator (NCR) of 37 kDa. This thesis will focus on the characterization of VISTA as the main objective. VISTA is a B7 family protein with one IgV domain and the closest evolutionary relation to PD-L1. It is expressed constitutively in the hematopoietic compartment with expression on naïve and stimulated CD4⁺ and CD8⁺ T-cells, Foxp3⁺ regulatory T-cells with the highest expression on tumor infiltrating lymphocytes (TILs). As a unique feature, VISTA is not only expressed as a receptor on T-cells, but also as a coinhibitory ligand on Antigen Presenting Cells (APCs) like macrophages, dendritic cells, neutrophils or monocytes with a higher expression compared to T-cells (Table 1.3.3.1). This expression pattern is similar for murine and human cells and the human and murine proteins show more than 80 % similarity (Flies et al. 2011; Kondo et al. 2016; Deng et al. 2016; Xu et al. 2018; Lines et al. 2014a).

Table 1.3.3.1: Surface expression of VISTA on human and mouse cell subsets evaluated by FACS analysis (Deng et al. 2016)

Cell Type	Surface VISTA expression	
	Human	Mouse
CD4⁺ naïve T-cells	+	++
CD4⁺ Foxp3⁺ T_{reg}	+	++
CD4⁺ memory T-cells	+	++
CD8⁺ T-cells	+	+
B cells	-	-
NK cells	-	-
Peritoneal macrophages	N/D	+++
Monocytes	+++	+++
Neutrophils	+++	+++
Dendritic cells	+++	+++

There are hints that VISTA could be expressed in intracellular compartments and VISTA seem to be endocytosed rapidly from the surface, but the amount of VISTA on the surface of myeloid cells remains stable (Deng et al. 2016; Liu et al. 2018).

The extracellular domain of VISTA has a high homology to PD-L1 (Figure 1.3.3.1 A2) (Lines et al. 2014b; Baksh und Weber 2015). The properties of the IgV domain of VISTA are highly conserved among the B7 family, (Deng et al. 2016) but VISTA seems to be a distant B7 member, because it shows four additional cysteines and the insertion of a loop in the IgV domain, which is absent in all other Ig-superfamily members (Figure 1.3.3.1 and Figure 1.3.3.2) (Xu et al. 2018).

The extracellular domain of VISTA can be shed at its juxtamembrane site. VISTA promotes the activation of the matrix metalloproteinase-2 (MMP-2) via increasing the expression of membrane type (MT)-1 MMP. Increased level of (MT)-1 MMP concomitant leads to the shedding of the extracellular VISTA domain and a higher invasive ability of tumor cells. Therefore, VISTA can contribute to tumor-invasive growth by regulation of surface MT-1 MMP (Sakr et al. 2010).

VISTA has a long highly conserved cytoplasmic tail which could enable a bidirectional signaling, similar to PD-L1, with receptor and ligand function (Lines et al. 2014a; Deng et al. 2016). The cytoplasmic tail does not contain any classical signal motifs but a potential binding site of a protein kinase c and proline residues, which could act as a docking station for adaptor proteins. In addition, the cytoplasmic domain contains several potential serine-, threonine- and tyrosine-phosphorylation sites (Figure 1.3.3.2). The cytoplasmic tail is crucial for VISTA signaling within the cell (Deng et al. 2016; Xu et al. 2018).

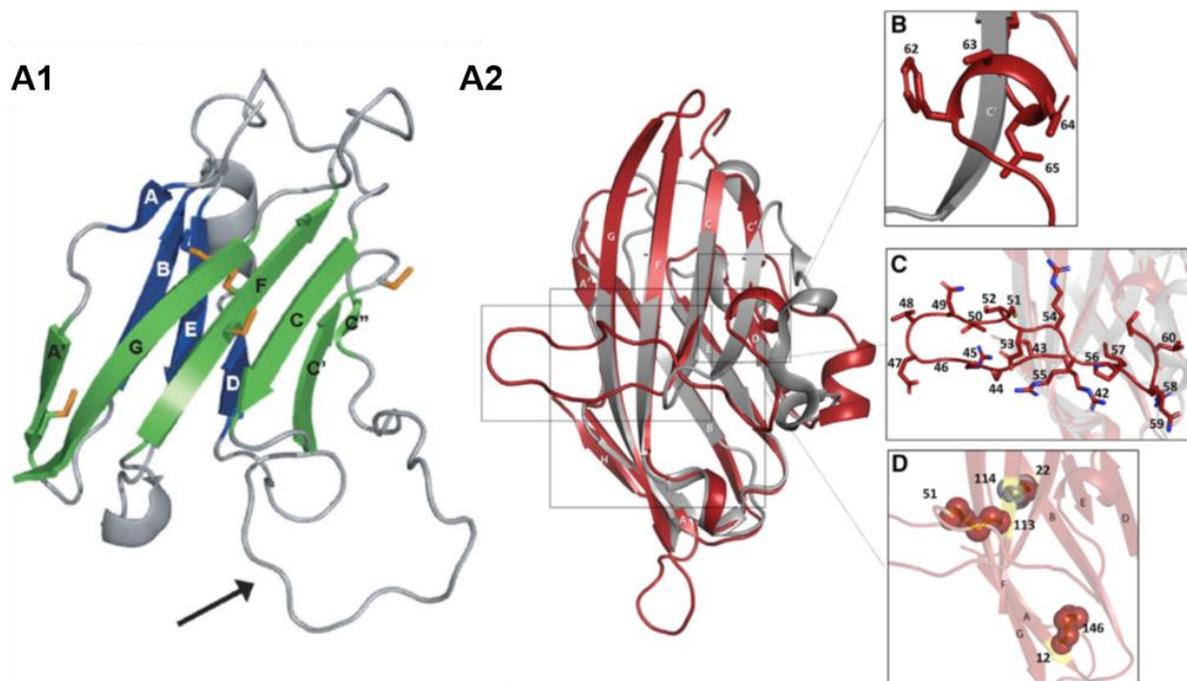

Figure 1.3.3.1: Structural analysis of VISTA (A1) A comparative protein structure model of mouse VISTA using PD-L1 as the template (Protein Data Bank accession no. 3BIS). The five cysteine residues in the Ig-V domain are illustrated as orange sticks. Based on this model, the VISTA Ig-V domain has the canonical disulfide bond between the B and F strands, as well as three additional cysteines, some of which can potentially form inter- and intramolecular disulfide bonds. An additional invariant cysteine is present in the stalk region following the G strand (not depicted). The β strands (A–G) are marked as green and blue. The C''-D loop is marked by an arrow (Wang et al. 2011).

A2) Structure of the extracellular domain of human VISTA (red) aligns with the IgV domain of human PD-L1 (gray), B) unique helix in VISTA in place of beta strand in PD-L1, C) Unique C-C0 loop in VISTA that extends from the beta-sandwich core, D) Disulfide bonds in VISTA (red spheres, yellow residues), including two unique disulfides (red spheres) in addition to conserved disulfide bond (C22, C114) between strands B and F (gray spheres) (Mehta et al. 2019)

Figure 1.3.3.2: Amino acid sequence of VISTA containing of signal peptide (blue), extracellular domain (yellow), transmembrane domain (orange) and intracellular domain (green)

VISTA is a direct transcriptional target of the tumor suppressor and transcription factor p53 which is activated by various cellular stress signals and induces several cellular core programs like cell-cycle arrest and apoptosis. As a tumor suppression key regulator, p53 is mutated in several tumor types but PD-1 and PD-L1 also show increased expression induced by p53 (Yoon et al. 2015).

Upregulation by p53 leads to a homophilic interaction of VISTA on macrophages and tumor cells which induces increased phagocytosis and clearance of VISTA-positive tumor cells, symbolizing an additional function of VISTA on APCs beside its immune-inhibitory role (Yoon et al. 2015).

But as a negative checkpoint regulator, the main function of VISTA is its function of immunosuppression.

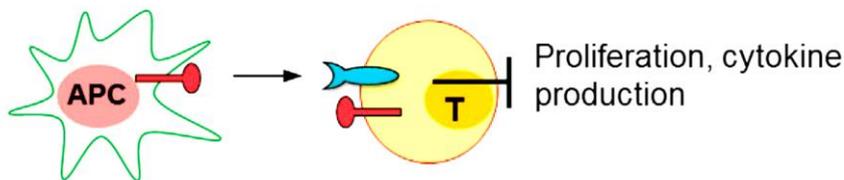

VISTA suppresses CD4⁺ and CD8⁺ T-cells similar to PD-L1 with a sustaining kinetics, leading to a reduced cytokine production (IL-10, TNF- α and IFN γ) (Baksh und Weber 2015). But VISTA could not only inhibit T-cell activation and proliferation, but also induces Treg differentiation (Lines et al. 2014a).

The importance of VISTA as a negative regulator can be observed in VISTA knockout (k/o) mice. A VISTA k/o leads to chronic inflammation and spontaneous activation of T-cells with hyper-production of inflammatory cytokines. That is an indication that the VISTA deficiency leads to a lower threshold for TCR-mediated activation against self-antigens (Liu et al. 2015). A knock-out of VISTA shows comparable results to a knock-out of PD-1, with loss of peripheral tolerance and T-cell activation, but because the double knock-out of both shows significant higher level of these phenotypes, it can be assumed, that both pathways work non-redundantly. Therefore it would be possible and useful to develop a therapy against both in combination (Liu et al. 2015).

VISTA deficiency on myeloid cells promotes their activation by upregulation of co-stimulatory molecules (CD80, CD40 and MHCII) and the production of cytokines (Ceeraz et al. 2017). The binding of VISTA to dendritic cells is sufficient to downregulate their activation, via the IL-23/IL-17-mediated inflammatory axis (Li et al. 2017).

With its expression on T-cells as well as APCs, the NCR VISTA can regulate the adaptive as well as the innate immune responses, qualifying VISTA as an interesting new target for checkpoint immune therapy (EITanbouly et al. 2019). But the expression of VISTA on APCs and T-cells assumes different functions for VISTA which should be explained further. For that I distinguished between the “ligand function” or “extrinsic T-cell function” of VISTA and the “receptor function” or “intrinsic T-cell function” (Figure 1.3.3.3) (Xu et al. 2018).

a T cell–extrinsic ligand function of VISTA

b T cell–intrinsic function of VISTA

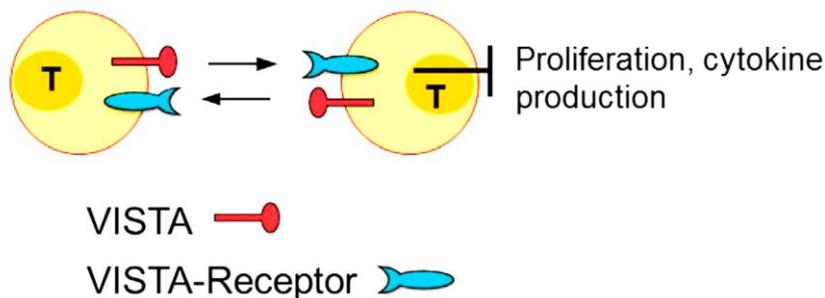

Figure 1.3.3.3: T-cell-extrinsic and -intrinsic function of VISTA (Xu et al. 2018). The extrinsic T-cell ligand function of VISTA is conveyed between the VISTA ligand on the Antigen Presenting Cell (APC) surface, binding the VISTA receptor on T-cells inhibiting proliferation and cytokine production of T-cells (a). For the intrinsic T-cell function VISTA ligand on the T-cell surface binds the VISTA receptor on T-cells inhibiting proliferation and cytokine production of the T-cells (b).

Extrinsic T-cell function/ Ligand function

VISTA, expressed on APCs, can engage an inhibitory receptor to suppress T-cell activation. In this setting VISTA is defined as a ligand with an extrinsic T-cell function (Figure 1.3.3.3 a) (Xu et al. 2018).

Endogenous VISTA on APCs has a synergistic inhibitory function as a ligand of CD4⁺ as well as CD8⁺ T-cells and acts independently of the PD-1 receptor on T-cells. That suggests that the VISTA ligand binds an unknown co-inhibitory T-cell receptor. The binding of the ligand VISTA by T-cells, suppresses the T-cell activation, -proliferation and -cytokineproduction of naïve and memory T-cells. In addition, the VISTA ligand

promotes the conversion towards Foxp3⁺ adaptive Tregs. For these effects on T-cells, the soluble VISTA ectodomain is also sufficient, symbolizing the ligand function of VISTA (Lines et al. 2014b; Kondo et al. 2016; Torphy et al. 2017; Wang et al. 2011; Lines et al. 2014a).

VISTA can bind itself in a homophilic interaction leading to suppression of T-cells. It is still unresolved if this inhibitory effect of the VISTA ligand is caused only by binding the VISTA receptor on T-cells. There is the possibility of another unknown inhibitory receptor on T-cells additionally (Liu et al. 2015; Yoon et al. 2015).

This co-inhibitory ligand function was also demonstrated in vivo, where VISTA expression on tumor cells overcame the vaccine-induced immunity of T-cells and led to tumor outgrowth (Wang et al. 2011).

Taking together, these results display the extrinsic T-cell function of VISTA, when expressed on APCs or tumor cells (Torphy et al. 2017; Xu et al. 2018).

Intrinsic T-cell function/ Receptor function

Endogenous VISTA shows inhibitory effects, not only as a ligand on APCs, but also as a co-inhibitory receptor on T-cells (Figure 1.3.3.3 b) (Lines et al. 2014b; Kondo et al. 2016). The VISTA receptor is expressed on CD4⁺ T-cells, CD8⁺ T-cells and Foxp3⁺ Tregs. Its intrinsic inhibitory role was displayed by VISTA deficient CD4⁺ T-cells and APCs. VISTA deletion on both cell types resulted in a much stronger proliferation of T-cells than on one cell type (Flies et al. 2014).

In addition, VISTA expression on T-cells is sufficient and required to inhibit allogeneic T-cell response in graft-versus host disease (Flies et al. 2011; Flies et al. 2014; Flies et al. 2015). T-cells express both, VISTA receptor and VISTA ligand which promote the peripheral differentiation of adaptive Tregs (Le Mercier et al. 2014; Lines et al. 2014a).

The binding of the VISTA-receptor impairs the phosphorylation of proximal signal and downstream molecules (Akt and Erk1/2) which disturbs the early TCR signaling. To activate the VISTA receptor on T-cells the soluble VISTA-Ig is sufficient (Liu et al. 2015).

Beside its homotypic interaction of the ectodomain (Prodeus et al. 2017; Yoon et al. 2015), there is one ligand of the VISTA receptor identified. V-set and immunoglobulin domain containing 3 (VSIG-3 or IgSF11) is an adhesion molecule that is responsible for homophilic, calcium-independent adhesion, with a high expression in the brain and testicles. In addition, VSIG-3 is upregulated in intestinal gastric cancer, colorectal cancer and hepatocellular carcinoma, displaying a new promising pathway for immunotherapy (Yang et al. 2017; Wang et al. 2019).

Sometimes it is difficult to distinguish between intrinsic, extrinsic, receptor and ligand function of VISTA. But it is certain that VISTA is a complex inhibitory protein with several functions on T-cells and Antigen Presenting Cells, which can tender the innate and adaptive immune response.

Antibody checkpoint therapy

Why consider VISTA for negative checkpoint therapy?

A VISTA blockade can be used as a broad-spectrum therapy against solid tumor in mouse models with better results than PD-1 (Lines et al. 2014a). The VISTA antibody enhances CD4⁺ and CD8⁺ T-cell mediated anti-tumor immunity in multiple tumor models (Le Mercier et al. 2014; Dankort et al. 2009). The efficiency of VISTA blocking is based on targeting multiple immune cell types. First, it enhances the infiltration, proliferation and effector function of CD4⁺ and CD8⁺ T-cells. Second, VISTA-blocking impairs the suppressive function of Foxp3⁺ Tregs and minimizes the induction of adaptive Tregs from tumor-specific naïve CD4⁺ T-cells. In addition, the VISTA-antibody activates tumor-associated myeloid DCs by upregulating CD80 and MHC-II, leading to enhanced production of cytokines (IL-12 and TNF- α). VISTA-antibody also reduces tumor-infiltrating myeloid-derived suppressor cells (MDSCs) (Le Mercier et al. 2014; Wang et al. 2018).

The VISTA antibody impairs tumor proliferation in mice, especially in combination with tumor vaccines. VISTA blockade still showed high anti-tumor efficiency even without measurable VISTA expression and despite high PD-L1 expression (Lines et al. 2014b).

The blockade of VISTA and PD-1 operate with identical functionality on T-cells. Both approaches reverse exhausted CD8⁺ T-cells in functional cytotoxic T-cells, but work non-redundantly (Liu et al. 2015, 2015; Kondo et al. 2016). Therefore, it would be possible and useful to develop a therapy in combination.

VISTA would open a therapeutic route for patients who don't respond to a PD-1 therapy or developed a resistance to PD-1 therapy. Possible resistance mechanisms are T-cell exhaustion, caspase-8 and β -catenin overexpression, PD-1/PD-L1 gene-amplification, MHC-I/-II mutations and downregulation of HLA-associated Antigen presentation. A combinatorial therapy with VISTA has the potential to overcome some of these resistance mechanisms (Dempke et al. 2017; Kakavand et al. 2017). Especially a combinatorial therapy with CTLA-4 (Kondo et al. 2016), PD-1 or its ligand PD-L1 could increase the response rate and prevent resistance.

In addition, it was discovered quite recently that VISTA is not only expressed on immune cells, but also on tumor cells. The VISTA expression on tumor cells partly correlates with the PD-1 and/or CTLA-4 expression, which punctuates the importance of a combinatorial therapy with VISTA (Wu et al. 2017; Wang et al. 2018; Mulati et al. 2019; Böger et al. 2017). VISTA positive tumors like OSCC (Wu et al. 2017), GC (Böger et al. 2017), ovaria and other gynecologic carcinoma (Mulati et al. 2019), melanoma (Mulati et al. 2019; Edwards et al. 2019), leukemia (Wang et al. 2018), HCC (Shrestha et al. 2018), prostate cancer (Gao et al. 2017) and pancreas cancer (Blando et al. 2019) would be ideal targets for a VISTA or combinatorial NCR therapy. Also esophageal adenocarcinoma (Loeser et al. 2019), pleural mesotheliomas (Muller et al. 2019) and renal cell carcinoma (Hong et al. 2019) are discussed as promising targets for anti-VISTA therapy.

These first insights provided a strong evidence for application of anti-VISTA antibodies in a clinical trial (clinicaltrials.gov, NCT02671955) on patients (Deng et al. 2016).

Of course, a VISTA-antibody therapy could also cause toxicities in patients. In mice, T-cell-mediated autoimmune encephalomyelitis accrued. Also cytokine-release syndrome, other autoimmune reactions and hyper-immune stimulation should be considered (Dempke et al. 2017; Granier et al. 2017; Marin-Acevedo et al. 2018).

In summary, several immune checkpoints are identified, and their antibodies are in different stages of pre-clinical and clinical development with promising results. Although the NCR antibody therapy has been a great breakthrough in cancer therapy, the immune-associated toxicity, the resistance to NCR treatment and the limited clinical benefit to a small subset of patients are the main challenges of this therapy. To improve the response rate, combinational therapy of multiple checkpoints or combination with anti-tumor vaccines should be pursued further. When considering VISTA for NCR therapy the newly discovered axis of VISTA-VSIG-3 should be investigated (Marin-Acevedo et al. 2018; Wang et al. 2019).

2 Objectives

Negative checkpoint regulators are well-studied targets for immunotherapy of tumors. But the checkpoint therapy against the two model NCRs PD-1 and CTLA-4 does not reach sufficient response rates in solid tumors. Therefore, there is still a need of new targets to reach higher response rates and to overcome therapy resistance. V-domain Ig suppressor of T-cell activation (VISTA) is a promising newly discovered negative checkpoint to overcome these issues. Due to its broad expression on different immune cells, tumor cells and tumor-infiltrating lymphocytes and its similar, but non-redundant functionality to PD-1. But to utilize VISTA for NCR therapy, a basic characterization of the protein is necessary. The literature so far focused on the classical NCR role and expression of VISTA on T-cells and in the tumor tissue. The expression of VISTA is even higher on APCs, but the function and behavior on this part of the immune system is barely investigated.

Therefore, the focus of this thesis will be the characterization of VISTA on APCs. For that, primary murine and human APCs, as well as monocytic celllines with and without VISTA overexpression are used. To classify my results, the characterization was done in comparison to the Jurkat T-cellline.

The thesis is divided into three parts.

- 1) The first part concentrates on the expression pattern of VISTA within different cells and cellular fractions. For that, the amount of VISTA expression was measured via qRT-PCR and IHC staining in different primary cells, celllines and tissue. For PD-L1 and CTLA-4 it is known that they are not exclusively expressed on the membrane but also in the nucleus or in vesicles. To investigate if VISTA is expressed exclusively on the cell surface or in other cellular fractions as well, different cellular fractions were isolated. In these fractions the VISTA expression was analyzed via IHC staining and Western Blot analysis. The results were discussed in comparison to the model NCRs PD-1/PD-L1 and CTLA-4.
- 2) The second part investigates the effects on the VISTA expression of part one after stimulation. For that, lipopolysaccharide (LPS) was used as an immunogenic stimulus. The expression pattern in different primary cells and celllines was again analyzed via qRT-PCR and IHC staining. In addition, primary murine BMDMs were seeded in different densities as a stimulus, and VISTA expression was analyzed via IHC staining.
- 3) The third part investigates the effects of VISTA overexpression on the immunological function of APCs. For that, the myeloid celllines HL-60 and THP-1 were transfected as VISTA-GFP cells and compared to the empty vector (EV) GFP control cells. We analyzed the effect of VISTA overexpression on the morphology and adhesion of the myeloid celllines w/o VISTA overexpression. Furthermore, we differentiated the myeloid celllines into macrophages to analyze the phagocytosis of VISTA overexpressing macrophages. We also performed phagocytosis assays the other way around, where primary macrophages engulfed the myeloid celllines w/o VISTA overexpression. In the last part our collaboration partner searched for possible interaction partners of

VISTA by GFP pull-out and mass spectrometry analysis. In addition, we checked some candidates for interaction in the qRT-PCR and FACS analysis with the myeloid celllines w/o VISTA overexpression.

3.2 Methods

3.2.1 Isolation of murine bone marrow cells and differentiation into bone marrow derived macrophages (BMDMs)

Macrophage medium:

- DMEM high glucose GlutaMAX media (4,5 g/L glucose)
- 10 % FCS
- 1 % Pen-Strep
- 20 ng/mL GM-CSF

The murine hind leg bones needed to be extracted intact and without organic materials like muscle or tendons. The bone ends were cut under the clean bench and the bone marrow was rinsed with a syringe in a sterile petri dish filled with sterile PBS. The bone marrow cells were collected with PBS in a 50 mL Falcon tube which was centrifuged for 5 min at 500 xg and RT to purify the bone marrow cells. Afterwards the cells were counted with a *Neubauer improved-Zählkammer* and seeded with a concentration of $1 \cdot 10^6$ cells/mL in a petri dish with the corresponding amount of Macrophage medium. On day two, the same amount of Macrophage medium was added gently to the dish. On day four, half of the whole medium was removed carefully and replaced by the same amount of fresh medium.

By day six-seven the cells were fully differentiated into a mixture of Antigen Presenting Cells (APCs) with mainly macrophages, so called bone marrow derived macrophages (BMDMs), and are about 80 % confluent.

All procedures were in accordance with the ethical standards as laid down in the 1964 Declaration of Helsinki and its later amendments.

All applicable inter-/national and institutional guidelines for the care and use of laboratory animals were followed.

3.2.2 Cell counting via *Neubauer improved-counting chamber*

The *Neubauer improved-counting chamber* was used with a coverslip as described in the protocol (<https://www.emsdiasum.com/microscopy/technical/datasheet/68052-14.aspx>). The cells were stained with 1:10 trypan blue and all cells that weren't stained and appeared bright and reflecting were counted.

3.2.3 Isolation of human peripheral blood mononuclear cells (PBMCs), CD14⁺ enrichment and differentiation into monocyte derived macrophages

Isolation of peripheral blood mononuclear cells (PBMCs)

The donor blood was collected in tubes with ~10mL blood per tube. Per tube 10 mL PBS was added in a 50 mL Falcon tube and mixed gently. 8 mL of the blood/PBS solution was overlaid on 4 mL Lymphoprep in a 15 mL Falcon tube and centrifuged at RT for 25 min at 400 xg without brakes. The interphases of one or two tubes were

collected in a 50 mL Falcon and filled up with PBS. The tube was centrifuged at RT for 5 min at 800 xg and the supernatant was removed. The pellet contained the peripheral blood mononuclear cells (PBMCs) and was resuspended in 2,5 mL media (RPMI+10 % FCS)/blood tube. The PBMCs were pooled in a 15 mL Falcon and the percentage of PBMCs in the population was analyzed via flow cytometry.

CD14⁺ enrichment via Magnetic Cell Separation (MACS) of Miltenyi Biotech

The CD14⁺ enrichment from PBMCs was done via a positive selection. The PBMCs were centrifuged at RT for 5 min at 500 xg, resuspended in 10 mL PBS and centrifuged again with the same conditions. The supernatant was removed, the cells were resuspended in PBS and magnetic CD14⁺ Microbeads: 20 µL Microbeads + 80 µL PBS/1 Mio PBMCs. The mixture was incubated for 15-45 min at 4 °C. 8 mL PBS was added after the incubation and the solution was centrifuged at RT for 5 min at 500 xg. The pellet was resuspended in 500 µL PBS and the cells were isolated with MidiMACS separation of Miltenyi Biotech.

The MidiMACS column was fixed on the MidiMACS magnet and calibrated with 500-1000 µL PBS. The cell-bead solution was added on the column and the flow through was collected in a FACS tube. The column was washed three times with 500-1000 µL of PBS and the flow through was collected in a FACS tube. For elution the MidiMACS column was removed from the MidiMACS magnet and the CD14⁺ cells were collected with a syringe with 1 mL PBS in a FACS tube. 1 mL medium (RPMI+10 % FCS) was added and the cells were counted via flow cytometry. The cells were seeded in 1*10⁶ cells/mL and differentiated to M0 macrophages.

This method was carried out at the UMCG in The Netherlands in accordance with the applicable rules concerning the review of Research Ethics Committees and informed consent.

3.2.4 Differentiation of the different macrophage subtypes

For this thesis several cells were differentiated into different macrophage types. All cells were first differentiated to M0 macrophages under the following conditions:

Table 3.2.4.1: conditions for macrophage M0 differentiation

cell type	stimulus	medium	duration
BMDMs	20 ng/mL GM-CSF	DMEM GlutaMAX+10 % FCS+ 1% Pen-Strep	6-7 days
Monocyte derived macrophages	50 ng/mL GM-CSF and M-CSF	RPMI-1640 + 10 % FCS	6-7 days
HL-60	1 µM PMA	RPMI-1640 + 10 % FCS	2-3 days
THP-1	1 µM PMA	RPMI-1640 + 10 % FCS	2-3 days

M0 macrophages can be further differentiated into M1, M2a or M2c macrophages via further incubation for 24 h with the following cytokines:

M1: 100 ng/mL LPS + 50 ng/mL IFN γ

M2a: 50 ng/mL IL-4

M2c: 50 ng/mL IL-10

3.2.5 Immunohistochemistry (IHC) protocol of primary murine cells and human celllines

The murine cells were fixed with 2 % PFA in TBS for 10 min. Afterwards the PFA solution was removed and the cells incubated in TBS+0,3 % Triton X-100 for 20 min. The cells were washed two times for 5 min in TBS+0,3 % Triton X-100 and then blocked with 10 % donkey serum in TBS for 1 h at RT. After two washing steps for 5 min in TBS+0,3 % Triton X-100 the primary antibody, which was diluted 1:200 in TBS, was incubated in a moist environment for 1-2 h at RT or over night at 4 °C. After primary antibody incubation the cells were washed three times for 5 minutes in TBS+0,3 % Triton X-100. The secondary antibody was diluted 1:500 in TBS and incubated in a dark and moist environment on the cells for 1-2 h at RT or over night at 4 °C. The washing was performed three times for 5 min in TBS+0,3 % Triton X-100 and two times in TBS. Finally, the cells were embedded in DAPI or DAPI free medium depending on the necessity of a nuclei staining and analyzed via fluorescent microscopy.

3.2.6 Immunohistochemistry (IHC) protocol of primary human cells

The human cells were fixed with 4 % PFA in PBS for 10 min. Afterwards the PFA solution was removed and the cells incubated in PBS+0,05 % Tween20 for 10 min. The cells were washed two times for 5 min in PBS+0,05 % Tween20 and then blocked with 10 % horse serum in PBS+0,05 % Tween20 for 1 h at RT. After two washing steps for 5 min in PBS+0,05 % Tween20 the Fc-blocker was added with 200 µg/mL PBS. The primary antibody, which was diluted 1:200 in Fc-PBS-blocking solution, was incubated in a moist environment for 1-2 h at RT or overnight at 4 °C. After primary antibody incubation the cells were washed three times for 5 minutes in PBS+0,05 % Tween20. The secondary antibody was diluted 1:200 in PBS+0,05 % Tween20 and incubated in a dark and moist environment on the cells for 1-2 h at RT or over night at 4 °C. The washing was performed three times for 5 min in PBS+0,05 % Tween20. For the nuclei staining the DAPI solution was diluted 1:2000 and added on the cells for 2 min. Three washing steps followed for 5 min in PBS+0,05 % Tween20 and two more washing steps with PBS. Finally, the cells were embedded in Vector Shield and analyzed via fluorescent microscopy.

3.2.7 FACS staining protocol

Per FACS sample at least 10 000 cells were used. Adherent cells were washed with PBS and trypsinated for several minutes at 37 °C to detach the cells. Afterwards the cells were harvested, centrifuged at 400 xg for 5 min and resuspended in 200 µL PBS. Suspension cells were directly centrifuged and resuspended in PBS. The fluorescent-labelled antibodies for FACS staining and FCR-blocking reagent were diluted 1:200 in the cell suspension and incubated for 45 min at 4 °C.

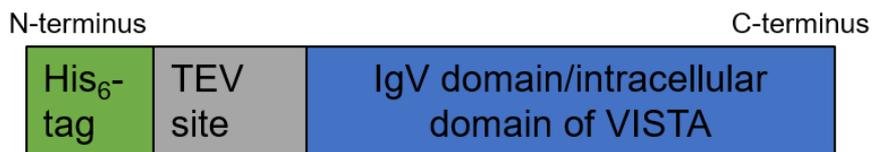

Afterwards the cells were washed twice with 1 mL PBS via centrifugation for 5 min at 400 xg. For measurement the cells were resuspended in 200 μ L PBS.

3.2.8 Cloning

Cloned constructs:

- petM-11-His-TEV-VISTA IgV (kanamycin resistant) (Figure 3.2.8.1 a)
- petM-11-His-TEV-VISTA intra (kanamycin resistant) (Figure 3.2.8.1 a)
- petGST1a-His-TEV-VISTA IgV (kanamycin resistant) (Figure 3.2.8.1 b)
- petGST1a-His-TEV-VISTA intra (kanamycin resistant) (Figure 3.2.8.1 b)

a)

b)

Figure 3.2.8.1: Cloning of VISTA constructs

The vector cards are attached in the appendix (Figure 7.1.1 and Figure 7.1.2).

The exons of the VISTA domains were optimized for *E.coli* expression and ordered.

General procedure:

1. The insert was amplified by PCR and digested for 1-2 h at 37 °C with NcoI-HF and KpnI-HF. The insert was purified from a 1,5 % agarose gel via FastGene Gel/PCR Extraction Kit by Nippon Genetics
2. The vector was digested with NcoI-HF and KpnI-HF, purified and 1 h dephosphorylated with the Quick CIP Kit from NEB at 37 °C. The phosphatase was deactivated at 80 °C for 2 min
3. Ligation of insert and vector was performed over night at 4 °C with the Rapid DNA Ligation Kit by Sigma-Aldrich
4. Transformation of the ligated construct by heat-shock in XL-1 blue cells
5. Plasmid DNA of some colonies was purified with FastGene Plasmid Mini Kit by Nippon Genetics and digested with NcoI-HF and KpnI-HF. Positive clones which showed an insert band on 1,5 % agarose gel were sequenced at GATC Biotech.

3.2.9 Protein expression and harvesting

The extracellular (IgV-VISTA) and the intracellular (intra-VISTA) domain of VISTA were heterologously expressed in BL21 or Rosetta *E. coli* bacteria cells. Both protein domains were expressed as fusion proteins. For the IgV-VISTA construct the pETM-11 Vector was transformed into BL21 or Rosetta *E. coli* bacteria cells, leading to a fusion protein of IgV-VISTA with a His-tag (six histidine at the C-terminus) for purification. The intra-VISTA construct needed a solubility tag for successful expression. For that the protein was cloned into the GST-vector leading to the fusion

protein intra-VISTA with His-tag and GST-tag. The plasmids were transformed into BL21 or Rosetta *E. coli* bacteria and plated on a LB Agar plate containing corresponding antibiotic (30 µg/mL kanamycin) overnight. One colony of the agar plate was used for a preculture of 5 mL autoclaved LB medium (Lennox) with corresponding antibiotic. The preculture was incubated overnight at 37 °C in a rotating incubator and transferred in a prewarmed 500 mL LB media flask with corresponding antibiotic and incubated at 37 °C and 180 rpm. When the OD₆₀₀ was between 0,6-0,8 1 mM isopropyl-β-D-thiogalactopyranoside (IPTG) was added and the protein expression was performed for 3-4 h. The bacteria suspension was centrifuged at 4 °C for 10 min at 6000 xg. The supernatant was discarded, the pellet was resuspended in 5 mL of PBS and collected in a 15 mL Falcon. The Falcon was centrifuged at 4 °C for 10 min at 10 000 xg and the supernatant was discarded. The pellet was frozen in liquid nitrogen and stored at -20 °C.

3.2.10 Purification of the extracellular IgV domain of VISTA

The IgV VISTA domain was purified via immobilized metal affinity chromatography (IMAC). The His-tag of the VISTA proteins can bind to Ni²⁺. Therefore, the IMAC columns were filled with NTA-agarose (Ni²⁺-NTA agarose ThermoFisher).

Before purification, the harvested cells needed to be lysed. For that, the cells were resuspended in 10 mL lysis buffer and sonified for 5 min ultrasonic sonifier. The suspension was centrifuged at 4 °C for 10 min at 50 000 g and the supernatant was discarded. The pellet was resuspended in equilibration buffer, shortly vortexed and sonified again for 10 s. Afterwards the solution was centrifuged again at 4 °C for 10 min at 50 000 xg. The supernatant was loaded twice on an equilibrated Ni²⁺-NTA agarose column.

Equilibration of the column was done with 10 column volume (CV) bi-dest and 10 CV of equilibration buffer.

For washing the different washing buffers 1-3 were added in sequence with 10 CV each on the column. To fold back the denatured IgV-VISTA protein on the column a Urea-gradient was used. 10 CV of each Urea buffer was used, and the gradient was performed from 8 M Urea to 0 M of Urea in descending order. The folded protein was eluted with 5 CV of Elution buffer.

The column was regenerated with 10 CV column-washing-buffer and 2x10 CV of bi-dest water afterwards, 10 CV EDTA and 2x10 CV of bi-dest water afterwards and 5 CV of NiCl₂-solution with 2x10 CV of bi-dest water afterwards. The column was stored filled with 20 % absolute Ethanol at 4 °C.

lysis buffer (10 mL):

25 mM Tris, pH 8
10 mM Imidazol, pH 8
150 mM NaCl, pH 8
10 µL mPIC protease inhibitor
10 µL DNase

Tip of a spatula of Lysozyme

equilibration buffer:

(in 8 M Urea)
25 mM Tris, pH 8
10 mM Imidazol, pH 8
150 mM NaCl, pH 8
10 mM β-2-Mercaptoethanol

elution buffer

25 mM Tris, pH 8
400 mM Imidazol
150 mM NaCl, pH 8

Table 3.2.10.1: Wash buffer for purification of the extracellular IgV Vista domain

Wash 1 (in 8M Urea)	Wash 2 (in 8M Urea)	Wash 3 (in 8M Urea)
25 mM Tris, pH 8	25 mM Tris, pH 8	25 mM Tris, pH 8
10 mM Imidazol, pH 8	10 mM Imidazol, pH 8	20 mM Imidazol, pH 8
150 mM NaCl, pH 8	500 mM NaCl, pH 8	150 mM NaCl, pH 8

Urea buffer in 8 M Urea:

25 mM Tris, pH 8
500 mM NaCl, pH 8
20 mM Imidazole, pH 8

Urea-free buffer in bi-dest:

25 mM Tris, pH 8
500 mM NaCl, pH 8
20 mM Imidazole, pH 8

Table 3.2.10.2: ingredients of the urea gradient buffers

Urea concentration	8 M	4 M	2 M	1 M	0,5 M	0 M
Urea-buffer	20 mL	10 mL	5 mL	2,5 mL	1,25 mL	0 mL
Urea-free buffer	0 mL	10 mL	15 mL	17,5 mL	18,75 mL	20 mL

Measurement of the protein concentration was done as described in the instructions with the Bradford reagent (Bradford 1976) in a polystyrene cuvette.

In comparison to this purification protocol dialysis was performed for renaturation of the protein. For that the Urea gradient was skipped and the unfolded protein was eluted in Elution buffer with 8 M Urea instead of water. The dialysis was performed two times for 2 h at 8 °C in dialysis buffer with a GSSG/GSH ration of 1:10

Dialysis buffer:

20 mM HEPES
100 mM NaCl
2 mM GSSG/GSH (Glutathione oxidized/reduced)
pH 7,5

3.2.11 Purification of the intracellular domain of VISTA

The intracellular VISTA domain was purified via immobilized metal affinity chromatography (IMAC).

Before purification, the harvested cells needed to be lysed. For that, the cells were resuspended in 10 mL lysis buffer and sonified for 5 min ultrasonic sonifier. The suspension was centrifuged at 4 °C for 10 min at 50 000 g and the supernatant was loaded on an equilibrated Ni²⁺-NTA agarose column.

Equilibration of the column was done with 10 column volume (CV) bi-dest and 10 CV of equilibration buffer.

For washing the different washing buffers 1-3 were added in sequence with 10 CV each on the column. The protein was eluted with 5 CV of Elution buffer.

The column was regenerated with 10 CV column-washing-buffer and 2x10 CV of bi-dest water afterwards, 10 CV EDTA solution and 2x10 CV of bi-dest water afterwards

and 5 CV of Ni²⁺-solution with 2x10 CV of bi-dest water afterwards. The column was stored filled with 20 % absolute Ethanol at 4 °C.

lysis buffer (10 mL):	equilibration buffer:	elution buffer

Measurement of the protein concentration was done as described in the instructions with the Bradford reagent (Bradford 1976) in a polystyrene cuvette.

3.2.12 Size exclusion chromatography (SEC)

In the size exclusion chromatography (SEC) mixture of proteins are separated by size. The renatured and purified IgV-VISTA domain was analyzed via SEC Purity Chrom bio5 by Knauer. For every column a size standardization was performed with standard proteins with known molecular weight. To analyze the dialysis purified samples the Biosep SEC S2000 (Phenomenex) was used. For all other experiments Superdex 75 10/300 GL (GE Healthcare) was used. After equilibration of the columns with SEC-buffer, the samples were centrifuged at 10 000 xg for 15 min at 4 °C before loading on the column with flowrate of 1 mL/min. 1 mL fractions were collected from 10 mL on and samples were taken for an SDS-PAGE.

<u>Molecular mass standards:</u>	<u>SEC-buffer:</u>
(in 5 mM NaPO ₄ + 150 mM NaCl, pH 7)	20 mM Hepes, pH 7,2
Catalase (232 kDa)	250 mM NaCl
Aldolase (158 kDa)	
Bovine serum albumin (67 kDa)	
Ovalbumin (43 kDa)	
Chymotrypsinogen A (25 kDa)	
Ribonuclease (13, 7 kDa)	

3.2.13 Transfection of VISTA-GFP overexpressing celllines

The production of the VISTA-GFP overexpressing celllines HL-60 and THP-1 was performed by the Experimental Hematology at the UMCG in Groningen. They used the

following lentivirus generation protocol to produce the 2e generation lentivirus. In addition the used the envelope pCMV-VSV-G (<https://www.addgene.org/8454/>) and packaging plasmid psPAX2 (<https://www.addgene.org/12260/>).

Lentivirus generation protocol

Day 1

- Coat T75 flasks with 5 ml 0.1% gelatine for 1-2 hours at RT.
- Aspirate off the gelatine and plate between 2×10^6 293T cells in 15 ml DMEM + 10% FCS and Pen-Strep into a gelatine coated T75. Incubate overnight at 37°C, 5% CO².

Day 2

Change media to 5 ml DMEM+ 10% FCS and Pen-Strep 2-6 hours before transfection. Transfect with Eugene:

Tube 1:

DMEM (-FCS and Pen-Strep)	100µl
Packaging construct (pCMV Δ8.91)	3µg
Glycoprotein envelope plasmid (VSV-G)	0.7µg
Vector construct	3µg

Tube 2:

- - DMEM (-FCS and Pen-Strep) 400µl
- Eugene 6 21µl

Add tube 1 to tube 2, flick gently to mix and allow complex formation for 20 minutes at RT.

Add mixture drop-wise to 293T cells, swirl gently and incubate overnight at 37°C, 5% CO².

Day 3

- Change medium on 293T cells to 6 ml HPGM and incubate overnight at 37°C, 5% CO².

Day 4

Harvest 6 ml virus from the T75 into a 10 cm plate (very gently since a lot of the cells will detach)

Pass over two 0.45µm filters (one filter for each 3 ml virus)

Freeze virus supernatant at -80°C in 500 µl aliquots.

The transfection efficiency was after several passages still at more than 70 % (controlled by flow cytometry).

3.2.14 Enzyme-linked Immunosorbent Assay (ELISA)

Detection of murine IL-6 via Sandwich-ELISA:

Primary antibody against the antigen was diluted 1:500 in PBS and bound to the microtiter plate with 50 μ L/well for 2 h at RT or at 4 °C overnight. The microtiter plate was washed two times with PBS-T (PBS+0,05 % Tween 20) and dried via tapping it on a tissue cloth. The blocking was performed with 1 % bovine serum albumin (BSA) in PBS for 30 min at RT with three PBS-T washing steps afterwards. The samples and cytokine standard were added for 4 h at RT or at 4 °C overnight. IL-6 standard was performed with 12 dilution steps from 60 ng/mL on, each with 1:3 dilution in medium. Afterwards the microtiter plate was washed three times with PBS-T. The antibody-bound antigen was recognized by the secondary biotin-labelled antibody which was diluted 1:1000 in medium and was added with 100 μ L/well for 1 h at RT. Washing was done three times with PBS-T. Streptavidin-conjugated horse radish peroxidase was diluted 1:1000 in PBS and added on the microtiter plate for 30 min at RT with 100 μ L/well. The microtiter plate was washed six times with PBS-T and dried via tapping the microtiter plate on a tissue cloth strongly. 50 μ L of Tetramethylbenzidine (TMB) solution was incubated for 5-10 min in the dark for the enzymatic color-reaction. The reaction was stopped with 50 μ L of 2 M H₂SO₄ and the amount of IL-6 was quantified at OD₄₅₀.

TMB solution: 1 pill of TMB was dissolved in 10 mL of buffer
Na₂HPO₄ 11,9 g/L
Na-Citrate 7,29 g/L
5 μ L of 30 % H₂O₂

3.2.15 Polyacrylamide gel electrophoresis

The sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), modified by Laemmli (Laemmli 1970), was used for all experiments to separate a protein composite in single proteins due to their molecular mass at 200 V, 299 mA and 15 W. For this discontinuous gel electrophoresis, two different gels were used, the stacking gel and the running gel, in the Mini-Protean-3-Electrophoresis system (BioRad). In the stacking gel the samples were concentrated and focused which leads to a better distinction and separation of the protein bands in the running gel. For running gel an Acrylamide-Bis concentration between 10-15 % was used, depending on the sample size. The running gel was overlaid by iso-butanol to prevent drying and a rough surface of the running gel. The iso-butanol was discarded after polymerization of the running gel and the stacking gel (5 % Acryl-Bis) was added with a comb into it. The samples were mixed with Laemmli sample buffer and the Electrophoresis was running with SDS Electrophoresis buffer.

SDS Electrophoresis buffer (10x):

30 g/L Tris
144 g/L Glycine
10 g/L SDS

Laemmli sample buffer (2x):

126 mM Tris/HCl, pH 6,8
20 % Glycerol
4 % SDS
0,02 % Bromphenolblue

running gel receipt (12 %):

1725 μ L H₂O
 1000 μ L Tris/HCl 1,5 M, pH 8,8
 1200 μ L Acrylamide-Bis solution 40%
 2,5 μ L TEMED
 21,5 μ L Ammonium persulfate (APS)

stacking gel receipt (5 %):

610 μ L H₂O
 250 μ L Tris/HCl 0,5 M, pH 6,8
 125 μ L Acrylamide-Bis solution 40%
 1,2 μ L TEMED
 12 μ L APS

To increase the accessibility for vesicle and pellet samples in the gel, Urea-gels were used for cell fractionation samples.

Urea-running gel receipt (10 %):

1725 μ L 8 M Urea
 1000 μ L Tris/HCl 1,5 M, pH 8,8
 1200 μ L Acrylamide-Bis solution 40%
 2,5 μ L TEMED
 21,5 μ L Ammonium persulfate (APS)

Urea-stacking gel receipt (5 %):

610 μ L 8 M Urea
 250 μ L Tris/HCl 0,5 M, pH 6,8
 125 μ L Acrylamide-Bis solution 40%
 1,2 μ L TEMED
 12 μ L APS

3.2.16 Western Blot

The Western Blot was performed with protein samples which were separated by SDS-PAGE before. The proteins were transferred to an equilibrated nitrocellulose (NC) by semi-dry blotting with 10 V, 15 W, 299 mA for 30 min or via Turbo Blot from BioRad. Equilibration of the NC membrane, the SDS gel and filter papers was performed via three steps of 5 min incubation in Towbin buffer (Towbin et al. 1979). All blocking, and antibody steps were performed in Roti-block instead of skim milk to prevent cross reaction of goat antibodies against the bovine milk. For reproducibility Roti-block was used for all antibodies.

After one washing step for 5 min in TBS the membrane was blocked in Roti-blocking solution (10x concentrate diluted in TBS-T) in TBS-T for 1 h at RT. The membrane was washed one time for 5 min in TBS-T and the primary antibody was diluted 1:1000 – 1:5000 in Roti-blocking solution before adding on the membrane for 1 h at RT or at 4 °C overnight. The primary antibody was removed via three washing steps in TBS-T. The secondary peroxidase-coupled antibody was used in 1:10 000- 1:20 000 dilution in Roti-blocking solution for 1 h at RT. The membrane was washed three times with TBS-T and two times with TBS. To detect the signal, the membrane was incubated for 5 min in enhanced chemiluminescence (ECL) substrate solution (1:1 Western Bright™ ECL and Western Bright™ Peroxide (advansta)). The luminescence was detected via Intas Chemocam Imager or BioRad Gel Doc XR+ System.

Towbin-buffer:

25 mM Tris
 192 mM glycine
 20% methanol p.a.

TBS:

20 mM Tris/HCl, pH 7.4
 154 mM NaCl

TBS-T:

0.05% Tween-20
 in TBS

3.2.17 Polymerase Chain Reaction (PCR)

The Polymerase Chain Reaction (PCR) was developed by Mullis (Bartlett und Stirling 2003) and is used to amplify DNA segments of interest. The amplification is exponentially and generates high copy number of DNA. The PCR consists of five important thermal steps:

1. Initialization: heating of the chamber to 94-96 °C to heat-activate the thermostable DNA polymerase
2. Denaturation: heating of the chamber to 94-98 °C to cause melting of the two DNA sample strands in single-stranded DNA
3. Annealing: temperature is lowered to 50-65 °C to anneal the two primers to each of the single-stranded DNA templates
4. Extension/elongation: Adapt temperature to activity optimum for the thermostable DNA polymerase to synthesize a new DNA strand out of the dNTPs
Step 2-4 need to be repeated for multiple cycles to amplify the DNA
5. Final elongation: This step is performed at 70-74 °C to elongate all remaining single DNA strands

For amplification of inserts for cloning, a PCR with a 25 µL or 50 µL batch with KOD polymerase was used. The KOD polymerase shows 3'→5' exonuclease-dependent proofreading activity resulting in a lower mutation frequency which is beneficial for cloning (Nishioka et al. 2001).

25 µL sample batch receipt:

2,5 µL 10x buffer
1,5 µL MgCl₂
2,5 µL dNTPs
0,5 µL per primer
0,5 µL KOD polymerase
16,5 µL DNase-free water
0,5 µL DNA

PCR program:

Lid: preheat 99 °C
Step 1: 94 °C 2 min
Step 2: 94 °C 20 s
Step 3: 57 °C 10 s
Step 4: 70 °C 30 s
Repeat Step 2-4 25 x
Step 5: 70 °C 10 min
Step 6: keep at 8 °C

For colony PCR bacterial material was added with a pipet tip instead of pure DNA

3.2.18 Real-time quantitative reverse transcription PCR (qPCR)

For the qRT-PCR, RNA was isolated from about 2 Million cells with the RNeasy® Plus Mini Kit from Qiagen. After measuring the RNA concentration via NanoDrop, 1000 ng of RNA were converted into cDNA with the iScript™ cDNA Synthesis Kit from BioRad. The cDNA was used for the qRT-PCR formulation (Ponchel et al. 2003):

- 5 µL Sybr Green/ sample
- 0,1 µL Primer Mix of forward and reverse primer/ sample, 25 µM per Primer
- 5 µL cDNA sample in RNase-free H₂O

Step 1: 95 °C for 3 min

Step 2: 95 °C for 5 s

Step 3: 58 °C for 15 s

Repeat Step 2-3 39 x

Step 4: 95 °C 10 s

Step 5: 65 °C 3 s

The quantification was calculated via reference genes (RPSII and RPL27) via the ΔC_T Method (Livak und Schmittgen 2001).

3.2.19 Phagocytosis assay

For the phagocytosis assay, it was measured how many macrophages engulfed tumor cells in a defined period of time. The phagocytosis assay was analyzed via microscope. The phagocytosis assays were performed with 10 000 macrophages/ well in a 96 well plate or with 40 000 macrophages/well in a 24 well plate and macrophage:tumor cell ratio of 1:1-1:5 over 2-4 h.

Phagocytosis of HL-60 and THP-1 macrophages:

Both celllines were used as green-fluorescent GFP-mutants, so the tumor cells needed to be stained in red. As tumor cells the B-cell lymphoma celllines SudHL4 or SudHL10 were used, because these are known celllines which are recognized and engulfed easily and with a high percentage. SudHL10 and SudHL4 were engulfed via HL-60 and THP-1 macrophages.

The tumor cells were stained with 1 µM IncuCyte® CytoLight Rapid reagent for 20 min in PBS at 37 °C. The staining was washed two times with 1 mL medium via centrifugation for 5 min at 450 xg. To activate and increase the phagocytosis, the tumor cells were mixed with 1 µg/mL Rituximab antibody. The medium of the macrophages was removed and the tumor cells were added in 100 µL/well for a 96 well plate and 300 µL/well in a 24 well plate. After phagocytosis for 2-4 h the tumor cells were removed and washed away carefully with PBS. Microscope analysis was performed directly.

Phagocytosis of monocyte derived macrophages:

The phagocytosis of monocyte derived macrophages was also analyzed by microscope. Undifferentiated HL-60 and THP-1 cells were used as tumor cells and stained with 5 μ M CFSE for 5 min at 37 °C in PBS. The staining was washed with two washing steps in 1 mL medium and centrifugation for 5 min at 450 xg. Afterwards the tumor cells were radiated in the cesium source with 6 Gy. After a recovery of the cells for 60-120 min at 37 °C the tumor cells were added on the medium-free macrophages. After an incubation time for 2-4 h the tumor cells were removed and carefully washed away. The macrophages were stained with a CD11b AF-594 antibody for 20 min 1:200 in medium while the presence of 1:200 FCR-blocking reagent. The antibody was removed via washing twice with fresh medium and the phagocytosis was analyzed via microscope.

3.2.20 Nucleus extract preparation

For a following mass spectrometer analysis four T165 flasks were used and one T75 flask for a Western Blot analysis.

The following protocol describes the buffer amounts for four T165 flasks.

The cells were centrifuged for 5 min at 1200 rpm at 4 °C in a 50 mL Falcon tube. Supernatant was discarded and the pellet was washed once in cold PBS with the same centrifugation step. The pellet was resuspended in 3 mL buffer A and transferred to two 2 mL Eppendorf tubes. The tubes were incubated on ice for 10 min before 75 μ L 10 % NP-40 (Igepal end concentration 0,5 %) were added per tube. The tubes were vortexed for 10 s and centrifuged for 1 min at 14 000 rpm at 4 °C to pellet the cell nuclei.

The pellets were resuspended in 700 μ L HS buffer each with filter tips and incubated on ice for 20 min with 10 second vortex steps every 5 minutes.

The extracted nuclei were centrifuged for 15 min at 14 000 rpm at 4 °C and transferred to a new pre-chilled 15 mL Falcon tube.

Buffer A:

10 mM HEPES/KOH pH 7.9
1,5 mM MgCl₂
10 mM KCl
1 mM DTT (added freshly)
1 x CLAP (added freshly)
0,1 mM PMSF (added freshly)

HS buffer:

20 mM HEPES/KOH pH 7.9
1,5 mM MgCl₂
420 mM NaCl
0.2 mM EDTA
25% Glycerol
1 mM DTT (added freshly)
1 x CLAP (added freshly)
0,1 mM PMSF (added freshly)

3.2.21 Co-Immunoprecipitation/GFP pull-out (Van den Boom 2016)

The co-immunoprecipitation of VISTA was performed via adding the VISTA antibody which was afterwards precipitated by Protein G beads. For the GFP pull-out GFP beads were used and added to the samples.

Two volumes of dilution buffer and three volumes of wash buffer were added to the samples (either cell extracts or nucleus extracts). For VISTA Co-IP 10 μ L of antibody per 5 mL cell suspension were incubated with the samples rotating over night at 4 °C. 50 μ L of GFP-trap MA beads (GFP pull-out) or protein G beads (Co-Immunoprecipitation) were equilibrated via adding 2 mL wash buffer, shortly spinned down and washed again before resuspension in 50 μ L of wash buffer/sample.

The beads were added to the samples and incubated rotating for 2 h at 4 °C. The samples were transferred to a pre-lubricated 1,5 mL Eppendorf tube in a magnetic rack. The beads were washed three times with 200 μ L wash buffer via resuspending the beads removed from the magnetic rack and then incubate the resuspended beads for 1 min in the magnetic rack before the supernatant is removed carefully.

Afterwards the beads were resuspended in 100 μ L wash buffer and transferred into a new 1,5 mL Eppendorf tube.

For elution the supernatant is removed, and the beads were resuspended 20 μ L elution buffer and 10 μ L 2x SDS samples buffer and heated at 100 °C for 10 min. The supernatant can be used for a Western Blot, Coomassie or mass spectrometer analysis.

Dilution buffer:

25 mM Tris/Cl pH 7.5
0,45% NP-40
1 x CLAP (added fresh)
0,1 mM PMSF (added fresh)

Wash buffer (in TBS):

0,3% NP-40/Igepal
1 x CLAP (added freshly)
0,1 mM PMSF (added freshly)

Elution buffer:

50 mM Glycine
pH 2,8

3.2.22 Cell fractionation and vesicle isolation

The cell fractionation was performed with one dense T25 flask of Jurkat cells, THP-1 Vista-GFP cells or HL-60 Vista-GFP cells. For BMDMs 2-4 dense 10 mL petri dishes were used, which corresponds to 20-40*10⁶ cells.

The frozen cell pellet was resuspended in 100 μ L TBS+100 mM KCl with 1 μ L PMSF. The cells were lysed mechanical with a syringe and a needle (22Gx1 ¼ 0,7x30 Nr. 12). The cell suspension was centrifuged for 10 min at 500 xg. The pellet was used as the “cell pellet” sample and resuspended in 100 μ L 1x Laemmli sample buffer.

The supernatant was centrifuged for 10 min at 1000 xg to isolate the nuclei. The Nuclei pellet was washed once in 100 μ L TBS+100 mM KCl with the same centrifugation step. Two μ L of the nuclei suspension were fixed on a microscope slide for IHC staining (3.2.6). The pellet was resuspended in 50 μ L 1x Laemmli sample buffer as “nuclei” sample.

The supernatant was centrifuged for 10 min at 3000 xg. This pellet was used as the “organelles” sample. The supernatant was used as the “cytosol” sample or added on top of a sucrose gradient for vesicle isolation.

The optimized sucrose gradient (Walker et al. 2016) for vesicle isolation was identified as 500 μ L 45 % sucrose+ 500 μ L 35 % sucrose+ 500 μ L 25 % sucrose with a centrifugation for 3-4 h at 41 000 xg (S52ST rotor). The sucrose was always diluted in TBS+100 mM KCl.

All sucrose fractions were harvested with a syringe in 1,5 mL Beckman Ultrifuge tubes and centrifuged for 1 h at 100 000 xg (S45A rotor). Two μ L of the vesicle suspension were fixed on a microscope slide for IHC staining (3.2.6). The pellets were resuspended in 25 μ L 1x Laemmli sample buffer as “vesicle” samples.

Early endosomes are primarily at the border between 35 % and 45 % sucrose whereas late endosomes and lysosomes accumulate at the border between 25-35 %.

3.2.23 Exosome isolation

For exosome isolation, cells of one dense T75 flask were cultured for three days in 15 mL of FCS-free medium. The medium was centrifuged for 10 min at 400 xg to remove the cells. The supernatant was centrifuged for 15 min at 2000 xg to remove the debris and nuclei. The supernatant was centrifuged for 30 min at 10 000 xg to remove all other organelles. This supernatant was added on 1 mL of 30 % sucrose in TBS+100 mM KCl and centrifuged for 2 h at 100 000 xg. The supernatant was used as “medium” sample. The pellet was resuspended in 500 μ L TBS+100 mM KCl and centrifuged in 1,5 mL Beckman Ultrifuge tubes for 1 h at 100 000 xg (S45A rotor). Two μ L of the exosome suspension were fixed on a microscope slide for IHC staining (3.2.6). The exosome pellet was resuspended in 25 μ L 1x Laemmli sample buffer.

This protocol was adapted from the “classical” way of (Patel et al. 2019).

3.2.24 Particle analysis with Python

To analyze the vesicles within the cells on microscope pictures a particle analysis was performed in Fiji (<https://fiji.sc/>; RRID:[SCR_002285](https://scicrd.org/RRID:SCR_002285); Schindelin et al. 2012). For that, the background corrected single color channels were converted into binary pictures and the vesicles separated via watershed. Afterwards the threshold was adjusted for best resolution of vesicles. In the particle analysis a size between 0-1,5 μ m² with 0,5-1,0 circularity was chosen. The coordinates of all particles were analyzed by Python (Python Software Foundation. Python Language Reference, version 2.7.13, Available at <https://www.python.org/>; (G. van Rossum 1995)) for colocalization. The colocalization plugins by Fiji would only give you a mean of colocalizing areas but can't count how many particles colocalize in the different channels. For that the following Python methods was written:

```
import csv
from collections import OrderedDict
```

```

with open('pixel2.csv', 'rb') as csvfile:
    r = csv.reader(csvfile, delimiter=';')
    amap = OrderedDict()
    bmap = OrderedDict()

    # Read all rows from CSV
    allrows = []
    for row in r:
        allrows.append(row)

    # Remove CSV header row
    allrows = allrows[1:]

    # Go through all rows and put values into dictionaries
    for i1,x1,y1,i2,x2,y2 in allrows:
        if len(x1) > 0 and len(x2) > 0:
            x1 = int(x1)
            x2 = int(x2)
            y1 = int(y1)
            y2 = int(y2)

            #print x1, y1
            amap[x1] = amap[x1]+[y1] if x1 in amap else [y1]
            bmap[x2] = bmap[x2]+[y2] if x2 in bmap else [y2]

results = []

#for k in amap.keys():
#    print k

for k,v in amap.iteritems():
    x1 = k
    x_range = range( x1 -2, x1 +3)

    for yvalue in v:

        results = []

        y1 = yvalue
        y_range = range( y1 -2, y1 +3)

        for x in x_range:
            for y in y_range:

                if x in bmap and y in bmap[x]:
                    results += [x,y]

        if len(results) > 0:
            results = [x1, y1]+results
            results = [ str(i) for i in results ]
            print ';'.join(results)

```

This method measures how many particles colocalize within a range of 2 pixel in x and y coordinate.

3.2.25 Colocalization study

The colocalization studies were performed by the ImageJ (1.52i) Colocalization Threshold method (Colocalisation_Analysis-3.0.4.jar). Briefly, a square of one color channel in the colocalizing area was flipped horizontal and vertical and the Pearson correlation coefficient R_{total} was calculated in comparison to the original picture.

3.2.26 Statistics

The results of this thesis were analyzed and evaluated by an analysis of variance (ANOVA). Depending on the sample size and number of conditions one factorial or two factorial ANOVA analysis was used. The null hypothesis of one factorial analysis is:

$$H_0: \mu_1 = \mu_2 = \dots = \mu_k$$

To check if the means of the sample groups are similar.

The alternative hypothesis is:

$$H_1: \mu_i \neq \mu_j$$

Samples groups with means that differ significantly on an alpha-level of 0,05 are marked with stars (*). For that the p-value of comparing samples was calculated and labelled with one to four stars from p-value <0,05 - <0,0001. The multiple comparisons of a two factorial ANOVA were evaluated by Sidak, of a one factorial ANOVA by Tukey. Confidence interval for both was 95 %.

In addition, the standard deviation of the samples is shown in black error bars.

Results of percental values could not be analyzed via ANOVA or comparable tests because of the lacking normal distribution. For other statistical tests the sample size was not sufficient, therefore we decided that a statistical analysis of my percental results is not possible in this setting.

4 Results

The results of this thesis can be distributed into three parts. In the first part 4.1 the general expression pattern of VISTA was summarized. For that a general characterization of the protein via SEC (4.1.1) was performed to check the hypothesis, if the extracellular domain of VISTA can build dimers. Afterwards we investigated the VISTA expression in different primary cells and celllines (4.1.2). The expression of VISTA in different cellular fractions like vesicles, nuclei and exosomes was summarized in 4.1.3. In the second part 4.2 the effects on the VISTA expression after a stimulus were summarized. We used LPS as an immunogenic stimulus (4.2.1), the inhibitors DAPT and TAPI-2 (4.2.2) and cell density (4.2.3) as stress stimuli. In the third part 4.3 the consequences of VISTA overexpression on APCs were investigated. For that we used myeloid VISTA-GFP overexpressing celllines. We observed effects on the morphology on the celllines (4.3.1), measured the varied adhesion (4.3.2) and phagocytosis (4.3.3 + 4.3.4). In addition, we checked some candidates of possible interaction partners (4.3.5). The differentiation control for murine BMDMs and the IHC antibody controls are attached in the appendix (Figure 7.2.5, Figure 7.2.6 and 7.2.7).

4.1 VISTA distribution in cell fractions and cell types

4.1.1 VISTA protein purification and characterization

After establishing a purification protocol for the insoluble recombinant IgV VISTA domain, the characterization was realized (laboratory supervision of B.Sc. thesis of Tanja Seifert). The results were summarized in (Tanja Seifert 2017).

The extracellular IgV-VISTA domain was expressed as petM11-His-TEV-IgV VISTA plasmid in two different *E.coli* strains BL21 and Rosetta. The amount of expression was checked with SDS-PAGE (Laemmli 1970). Samples of two flasks were taken every hour (Figure 4.1.1.1).

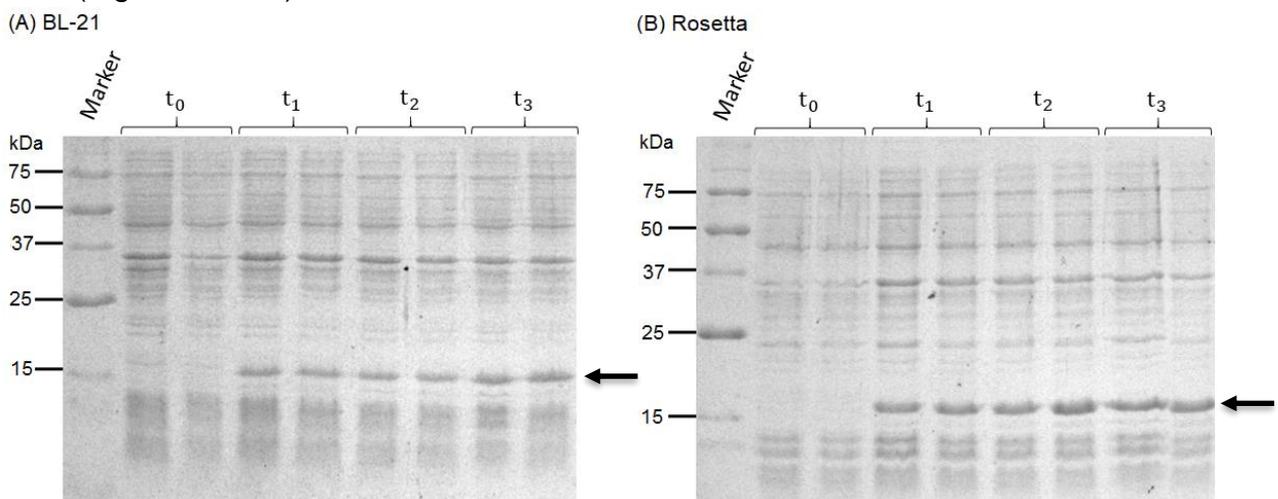

Figure 4.1.1.1: Coomassie staining of the IgV-VISTA-TEV-His6 (19 kDa) expression in (A) BL-21 and (B) Rosetta in 15 % SDS gels. Samples were taken before induction (t₀), after one (t₁), two (t₂) and three (t₃) hours of expression

One can see for BL-21 (A) and Rosetta (B) bands after induction (t_{1-3}) at around 18 kDa which were not visible before induction (t_0) (arrows in Figure 4.1.1.1). The theoretical molecular mass of the fusion protein IgV-VISTA-TEV-His6 is 19 kDa and fits with the expression bands. The expression bands were a little bit stronger in Rosetta bacteria, so the purification was performed with Rosetta expression samples (Figure 4.1.1.2).

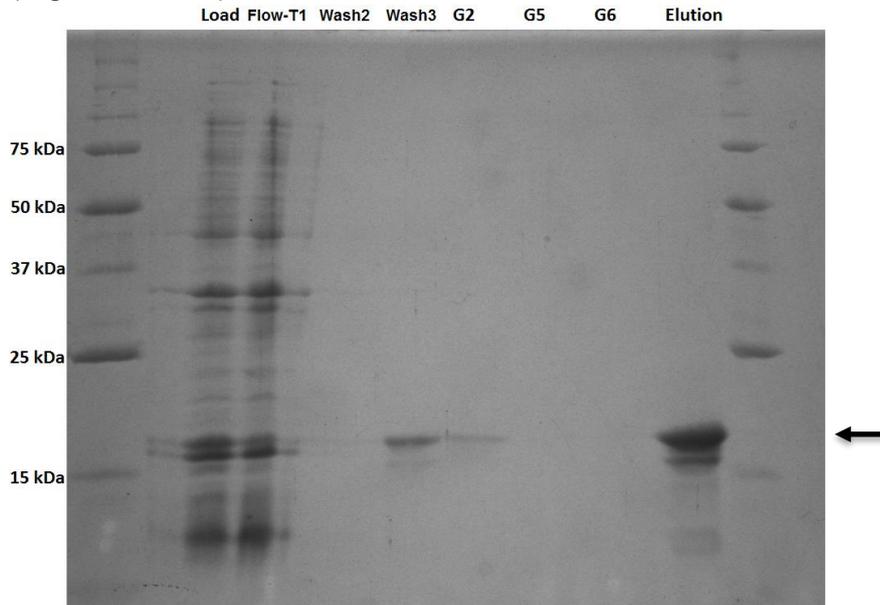

Figure 4.1.1.2: Coomassie staining of selected samples of the Immobilized metal ion affinity chromatography (IMAC) purification and renaturation of IgV-VISTA-TEV-His6 on a Ni^{2+} -NTA agarose column

The load was added three times to the column (Load, Flow-Through 1+2) and washed with three different wash buffers (Wash 1-3) before the Urea gradient was performed (Gradient 1-6). One can see a binding of IgV-VISTA protein (19 kDa) to the column in the flow-through fractions. The washing and gradient caused a small loss of the protein of interest but also increased the purity. After washing and gradient the renatured IgV-VISTA-TEV-His6 protein was eluted. The purified protocol showed a double band (arrow in Figure 4.1.1.2) which is probably due to the imperfect posttranslational modifications in *E.coli*. The protein concentration was quantified via Bradford-Assay with a BSA calibration curve. The yield of purification was 270 $\mu\text{g}/\text{mL}$ IgV-VISTA-TEV-His6. One can see a little bit of degradation of the protein in smaller bands, but the main band showed the right size for the fusion protein of interest. For a characterization the smaller bands were disregarded.

The protein was characterized by SEC (Figure 4.1.1.3) to check the size distribution of IgV-VISTA in solution. In comparison to this purification protocol, dialysis was performed for renaturation of the protein and characterized by SEC (Figure 4.1.1.4). The raw chromatograms and the chromatograms of the standard proteins are in the appendix (Figure 7.2.1, Figure 7.2.2., Figure 7.2.3 and Figure 7.2.4).

VISTA-IgV after dialysis

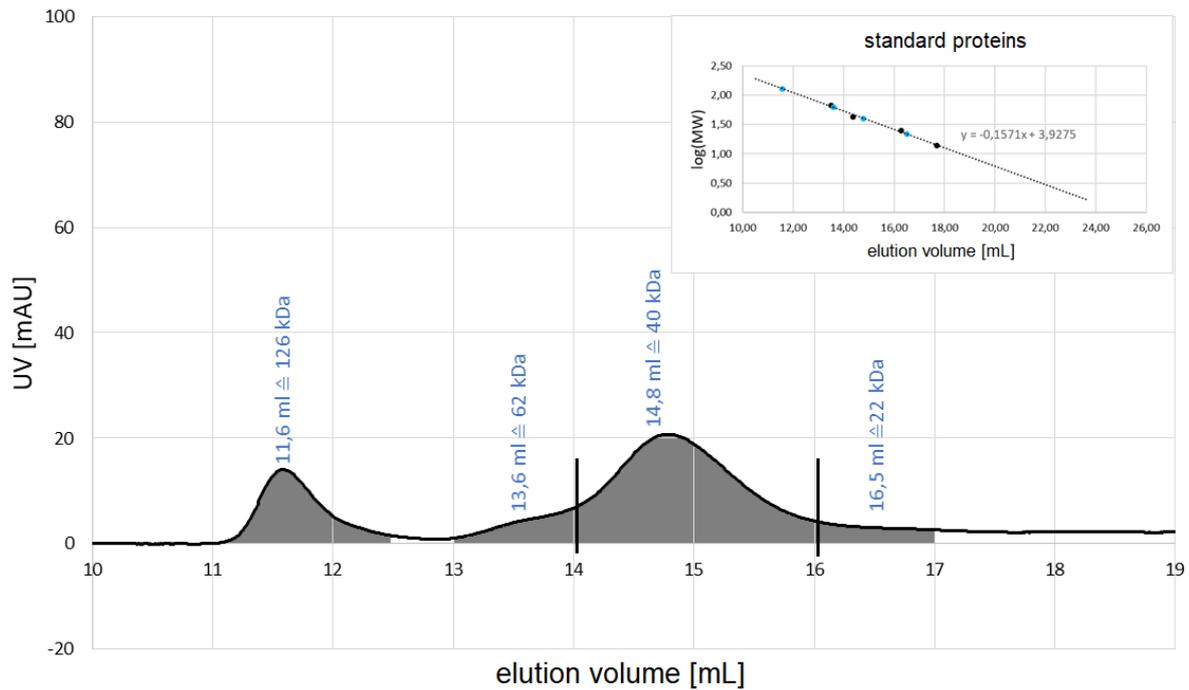

Figure 4.1.1.3: Analytical size exclusion chromatography (SEC) of 500 μ L IgV-VISTA protein sample (847 μ g/mL) after renaturation via dialysis. Peaks were analyzed by the calibration line which was made by calibration with standard proteins (upper right corner, black dots). The peaks were added on the calibration line in blue. The chromatogram was linear baseline corrected. The raw data is in the appendix (Figure 7.2.3)

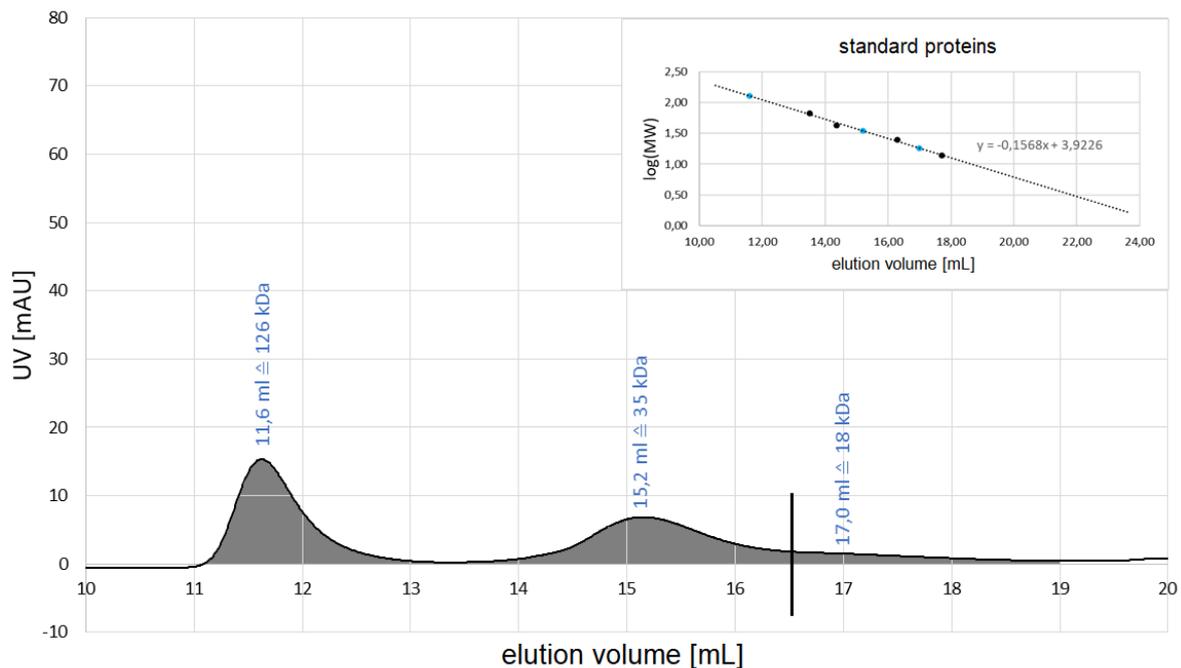

IgV-VISTA after renaturation on Ni²⁺-column

Figure 4.1.1.4: Analytical size exclusion chromatography (SEC) of 500 μ L IgV-VISTA protein sample (564 μ g/mL) after renaturation on Ni²⁺-column. Peaks were analyzed by the calibration line which was

made by calibration with standard proteins (upper right corner, black dots). The peaks were added on the calibration line in blue. The chromatogram was linear baseline corrected. The raw data is in the appendix (Figure 7.2.4)

The chromatograms (Figure 4.1.1.3 and 4.1.1.4) showed peaks at an apparent molecular mass of 126 kDa and 35-40 kDa which is ending in a shallow shoulder with a peak of 18-22 kDa before reaching the basis line. Samples after dialysis showed a second shoulder with a peak at an apparent molecular mass of 62 kDa (Figure 4.1.1.3). Both chromatograms demonstrated the strong tendency of IgV-VISTA to build dimers (theoretical molecular weight of 38 kDa), trimers (62 kDa) and even oligomers (126 kDa). The monomer of 19 kDa is underrepresented and not the primary form of the IgV-VISTA domain.

The eluate of all fractions was collected and analyzed via SDS-PAGE (Figure 4.1.1.5).

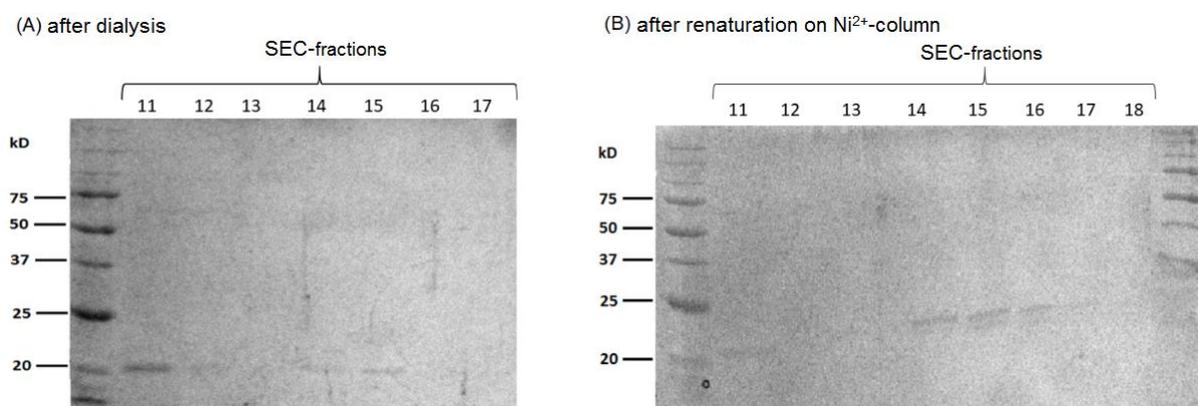

Figure 4.1.1.5: SEC-fractions (A) after dialysis and (B) after renaturation on Ni²⁺-column on SDS-gels. The fractions were numbered by retention volume from 11 mL on

Fractions with bands in the SDS-gel corresponded with the peaks in the chromatogram. All fractions showed only one band of the right size of around 19 kDa of IgV-VISTA-TEV-His. Therefore, all peaks in the chromatograms contributed to different IgV-VISTA size species. The weak bands were due to dilution during fractionation by SEC.

To analyze the peaks the integrals of the peaks (grey) were measured and compared (Table 4.1.1.1).

Table 4.1.1.1: Results of the numerical integrals of the two shown chromatograms (Figure 4.1.1.3 and Figure 4.1.1.4)

	after dialysis		renaturation on Ni ²⁺ -column	
	absolute area	proportion to the whole area	num. integral	proportion to the whole area
Peak 1 oligomer	495,04	23,58%	296,97	46,49%

Peak 2 trimer	90,26	4,3%	-	-
Peak 3 dimer	1475,46	70,28%	317,98	49,78
Peak 4 monomer	38,65	1,84%	23,87	3,74

The proportion of the first peak was smaller after renaturation of IgV-VISTA-TEV-His6 with dialysis, displaying that the renaturation via dialysis led to more soluble protein, whereas the renaturation on the column caused more non-soluble IgV-VISTA aggregates.

The highest peak for both renaturation methods was the dimer of IgV-VISTA. This showed the high tendency and capability of VISTA to build dimers. The monomer and the trimer were highly underrepresented compared to the dimer and not the preferred and most abundant species of IgV-VISTA. This confirmed the former findings and hypothesis that IgV-VISTA tends to build dimers (Liu et al. 2015; Yoon et al. 2015).

4.1.2 VISTA expression in different cell types

To get an overview of the VISTA amount in common celllines of T-cells and Antigen Presenting Cells, we tested the following celllines by qRT-PCR:

Table 4.1.2.1: Overview over celllines tested for NCR expression

Name of celllines	Cell type	Disease origin
Jurkat	T-cell lymphocytes	Acute T-cell leukemia
THP-1	Monocytes	Acute monocytic leukemia
K562	undifferentiated	chronic myelogenous leukemia
U937	Monocytes	Histiocytic lymphoma
NB4	Promyeloblasts	Acute promyelocytic leukemia
HL-60	Promyeloblasts	Acute promyelocytic leukemia
OCIAML3	Myeloblasts	Adult acute myeloid leukemia
MOLM13	Myeloblasts	Adult acute myeloid leukemia

VISTA expression was calculated via reference genes (RPSII and RPL27) via the ΔC_T Method (Livak und Schmittgen 2001) (Figure 4.1.2.1).

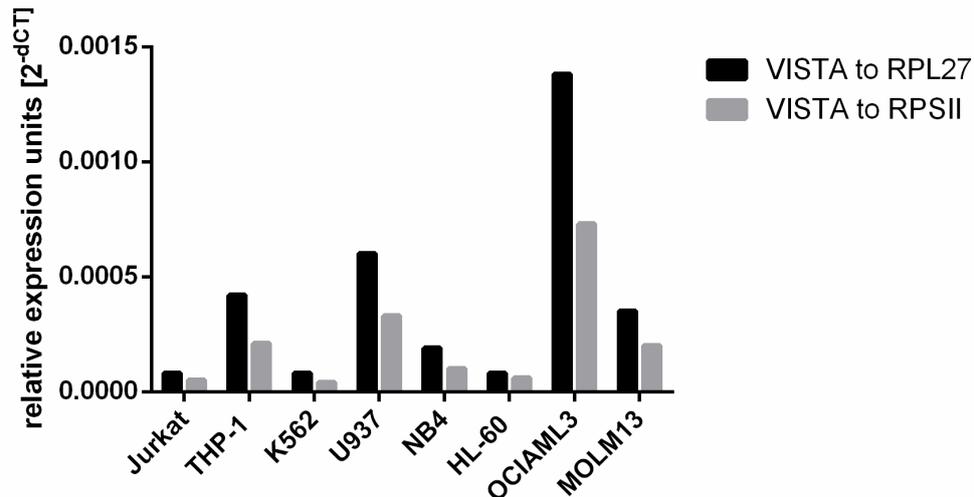

Figure 4.1.2.1: qRT-PCR analysis of VISTA expression on different celllines, n=1 in triplicates

One could observe a difference regarding the amounts of VISTA between the two reference genes. Nevertheless, both showed the same trend and pattern. The celllines with the highest VISTA expression were OCIAML3, U937 and THP-1. Especially the undifferentiated celllines K562, HL-60 and NB4 showed a weak VISTA expression. Overall, the expression of VISTA was stronger in Antigen Presenting Cells than in T-cells (Jurkat), like expected. All celllines were developed from tumor cells and did not show high expression of VISTA, especially in comparison to primary cells (Figure 4.1.2.3). But in comparison to PD-L1 (Figure 4.1.2.2) which was mainly expressed on Antigen Presenting Cells and upregulated on some tumor cells, the VISTA expression was more prominent. PD-L1 showed 100x less expression than VISTA on the celllines tested. The celllines with the highest PD-L1 expression were NB4, THP-1 and U937.

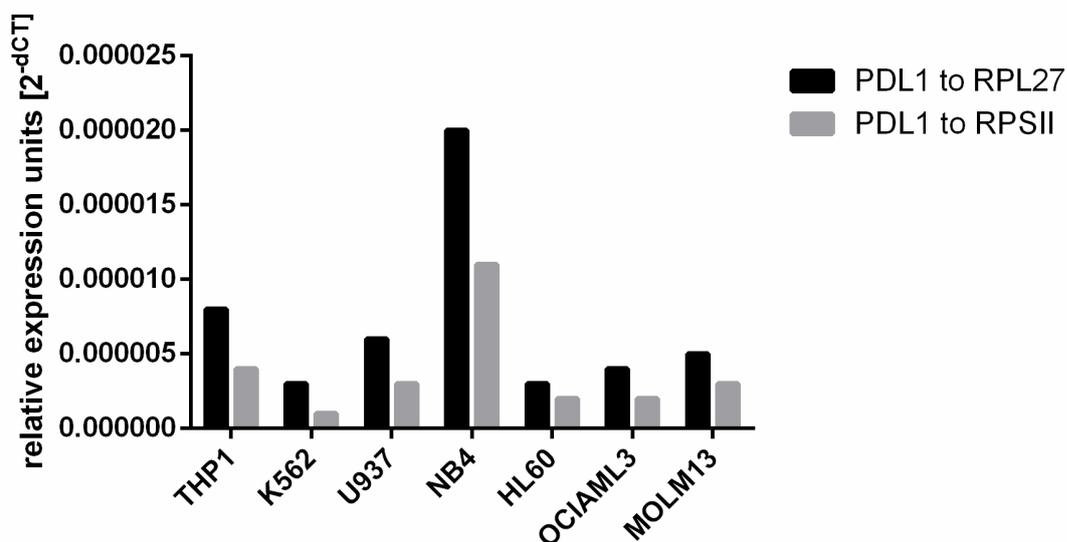

Figure 4.1.2.2: qRT-PCR analysis of PD-L1 expression on different celllines, n=1 in triplicates

The VISTA expression was much higher on primary cells (Figure 4.1.2.3) than on celllines. On primary cells the expected higher VISTA expression on macrophages compared to T-cells was also more pronounced. But depending on the peripheral blood donor the amounts of VISTA expression differed. PD-L1 (Figure 4.1.2.4) showed the

same high expression on primary macrophages compared to T-cells. Except for the macrophage donor II the amounts of VISTA and PD-L1 were within the same range.

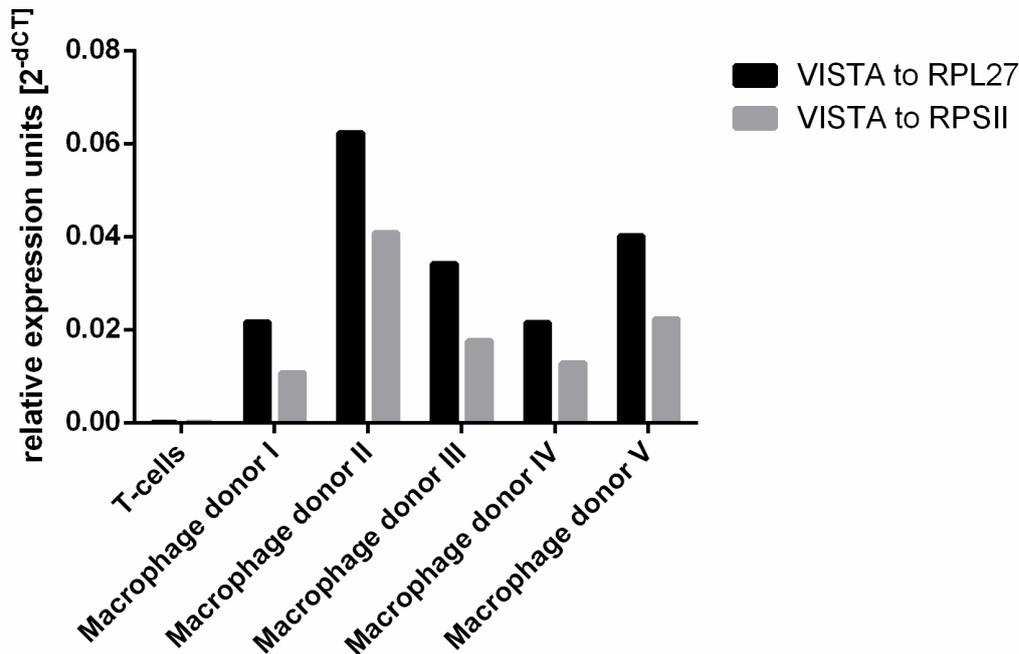

Figure 4.1.2.3: qRT-PCR analysis of VISTA expression on different primary cells, n=1 in triplicates

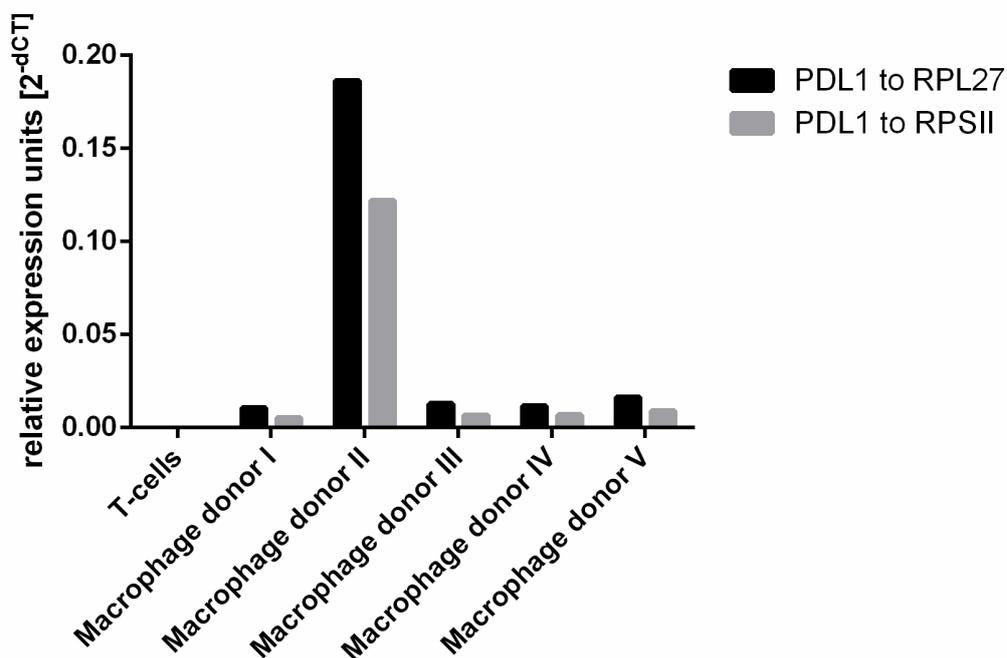

Figure 4.1.2.4: qRT-PCR analysis of PD-L1 expression on different primary cells, n=1 in triplicates

As a functional tool, the celllines THP-1 and HL-60 were transfected with the fusion protein VISTA-GFP. To measure the success of VISTA overexpression, a qRT-PCR with the reference gene RPSII was performed (Figure 4.1.2.5). The overexpression was successful for both celllines but 1,5 times stronger in HL-60 cells. For THP-1 the increase of expression was 45-fold higher than the wildtype cells and for HL-60 cells 64-fold compared to the empty vector control. Both VISTA overexpressing celllines

showed a higher or comparable VISTA expression to primary macrophages (Figure 4.1.2.3).

4.1.3 VISTA expression in cellular fractions

VISTA in vesicles in murine BMDMs

VISTA staining of primary murine BMDMs showed a dot-like vesicular pattern, which we observed with all anti-VISTA antibodies. These dots aligned on tubulin fibers confirming the assumption that VISTA is stored in vesicles (Figure 4.1.3.1). We confirmed presence of VISTA on the cell surface of APCs in agreement with VISTA being a membrane protein. However, VISTA did not show a strong staining of BMDM plasma membranes. This could be due to a concentrated staining of dots representing vesicles and a more scattered staining of VISTA on the cell surface leading to images of lower fluorescence intensity. To confirm that the dot-like staining pattern of VISTA is due to expression in vesicles, a colocalization analysis of deconvoluted confocal pictures with three different vesicle markers were performed (Figure 4.1.3.2). The transferrin receptor CD71 is an established marker for endocytic vesicles whereas perforin stains secretory granules. Perforin and the transferrin receptor CD71 were chosen as marker proteins, because another NCR, the model CTLA-4 colocalizes with both markers (Linsley et al. 1996). As a third marker we employed Snap-25, which stains vesicles in the neuronal cells, but also in monocytic cells like THP-1 cells and B-cells (Uhlen et al. 2017; Gonelle-Gispert et al. 2000). Staining of all three vesicle markers and of anti-VISTA antibodies resulted in a colocalization pattern that is best seen in column b of Figure 4.1.3.2. The most intense labelling of vesicles was observed with anti-perforin antibodies as perforin is highly expressed in macrophage vesicles. In order to distinguish apparent colocalization due to superimposed overlaying images

from an image indicating real colocalization in one cell layer, we used flipping controls of corresponding sections thereby confirming presence of VISTA in vesicles (Figure 4.1.3.3).

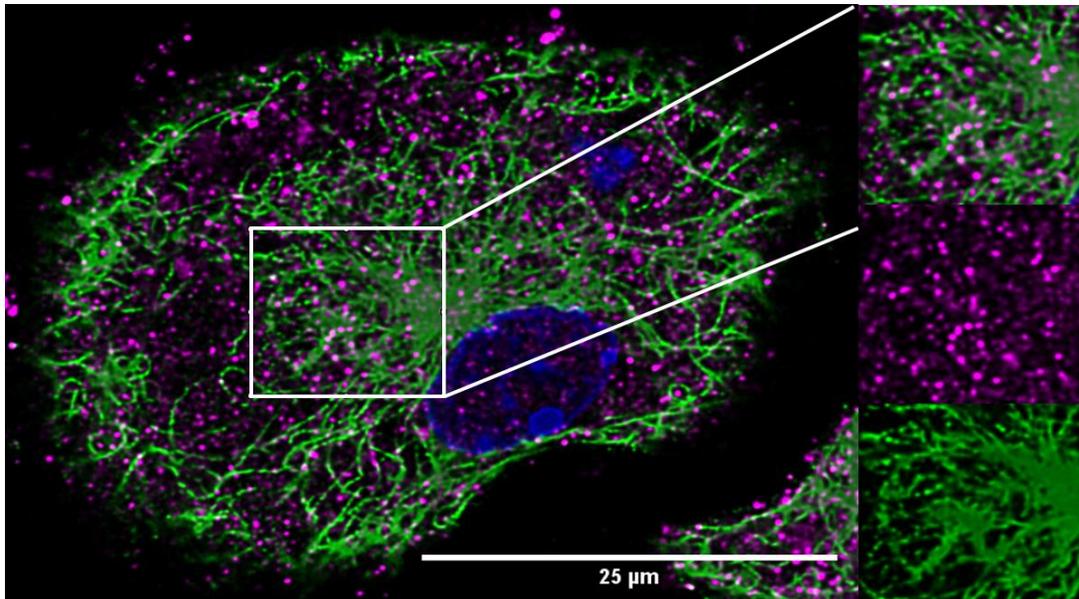

Figure 4.1.3.1: BMDM deconvoluted Tubulin (green), VISTA N12 (magenta) and Dapi (blue) staining

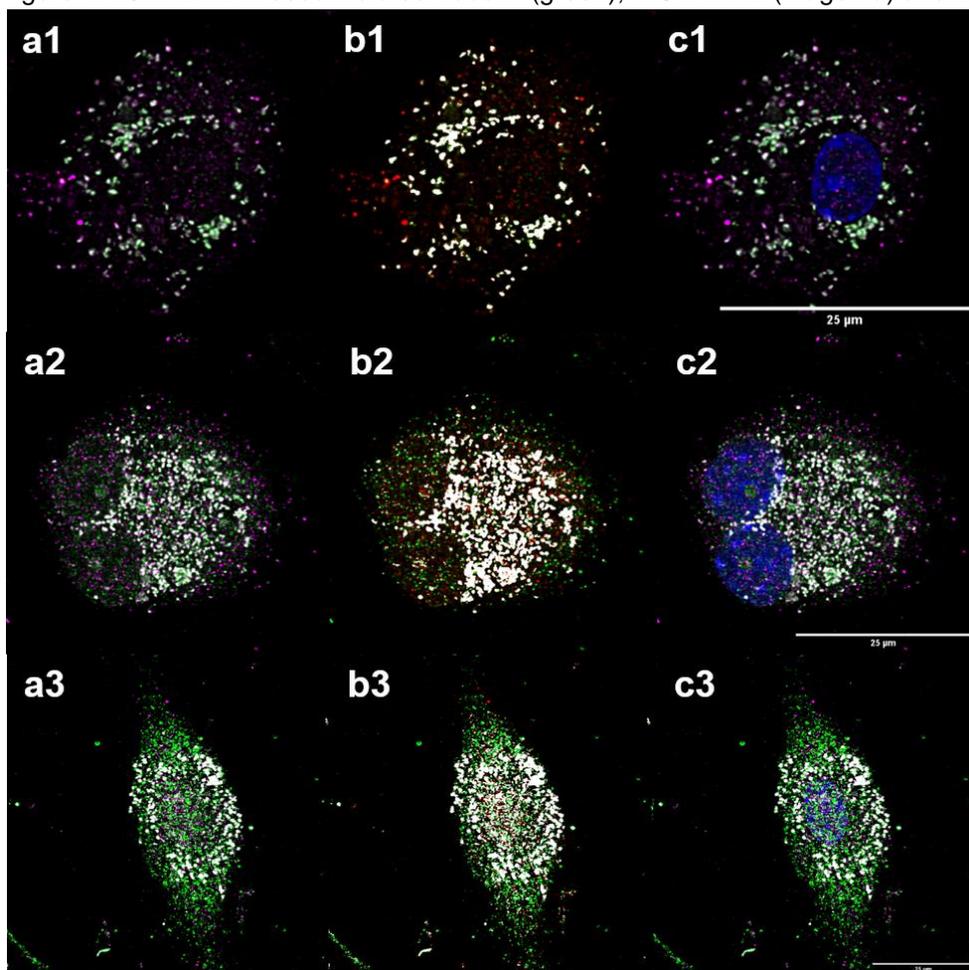

Figure 4.1.3.2: BMDM deconvoluted VISTA S14 (magenta), vesicle marker (green) and Dapi (blue) (column c) staining, without Dapi (column a), corresponding colocalizing pixel (column b). Vesicle marker Transferrin receptor (CD71) in row 1 (Rtotal: 0,786, flipped horizontal: 2,12 %, flipped vertical:

1,55 %), vesicle marker Perforin in row 2 (Rtotal: 0,779, flipped horizontal: 2,98 %, flipped vertical: 12,29 %) and vesicle marker Snap-25 in row 3 (Rtotal: 0,379, flipped horizontal: 0,001 %, flipped vertical: no correlation found).

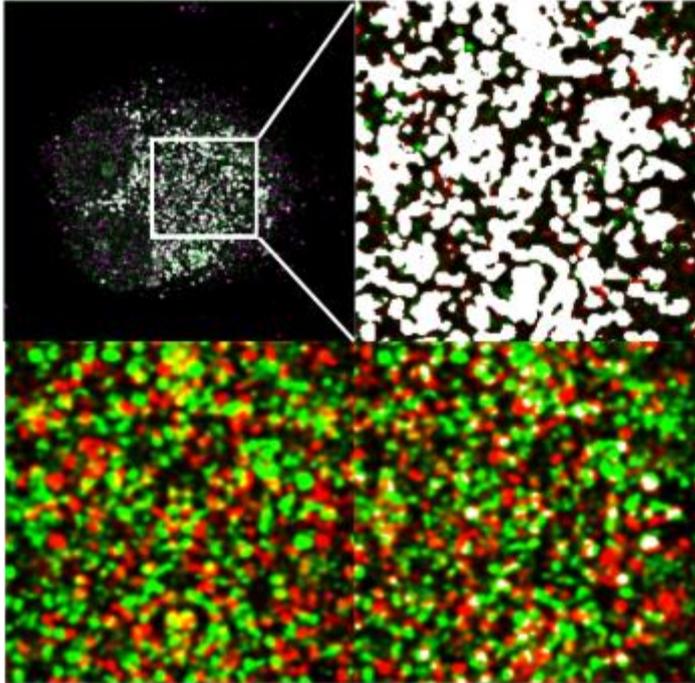

Figure 4.1.3.3: BMDMs deconvoluted Perforin (green) and VISTA S14 (magenta) staining colocalization analysis of the section (right top), section flipped horizontal (bottom left, Rtotal: 2,98 %), section flipped vertical (bottom right, Rtotal: 12,29 %)

In addition, we isolated BMDM derived vesicles on a sucrose gradient and tested the presence of VISTA in different fractions. Vista was detected in a fraction containing 25 % (w/w) sucrose as an expected molecular mass of 37 kDa (Figure 4.1.3.4). VISTA appears with a double band in the Western Blot due to the glycosylation.

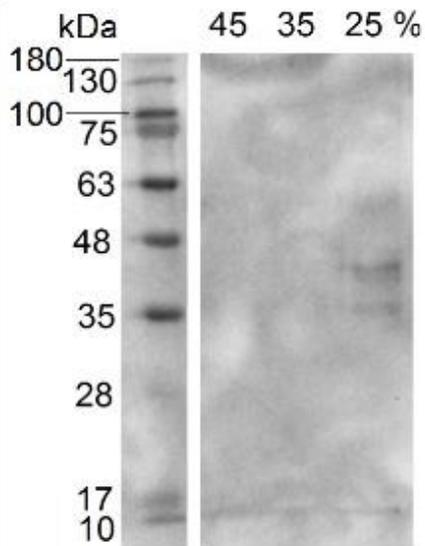

Figure 4.1.3.4: Western Blot of 4×10^6 BMDMs on a vesicle gradient of different sucrose concentrations (25, 35 and 45 % sucrose in TBS+100 mM KCl). D1L2G primary VISTA antibody 1:2000 for 120s

Vesicular VISTA in human monocyte derived macrophages

We next asked whether a similar cellular distribution of VISTA is present in human APCs using human primary monocyte derived macrophages. The VISTA staining of monocyte derived macrophages also showed a vesicular dot-like pattern (Figure 4.1.3.5) and was observed in M0 macrophages subtype but also for M1, M2a, and M2c monocyte derived macrophages (not shown). These dots also aligned on tubulin fibers and staining of VISTA was much stronger than staining of the cell surface, which supports our hypothesis of VISTA expression in vesicles. We proved VISTA staining in vesicles using the same three vesicle markers as for murine BMDMs, the transferrin receptor (Figure 4.1.3.6), perforin and Snap-25 (not shown). Staining of these markers was positive in primary monocyte derived macrophages in all macrophage subtypes M0, M1, M2a (not shown) and M2c (Figure 4.1.3.6).

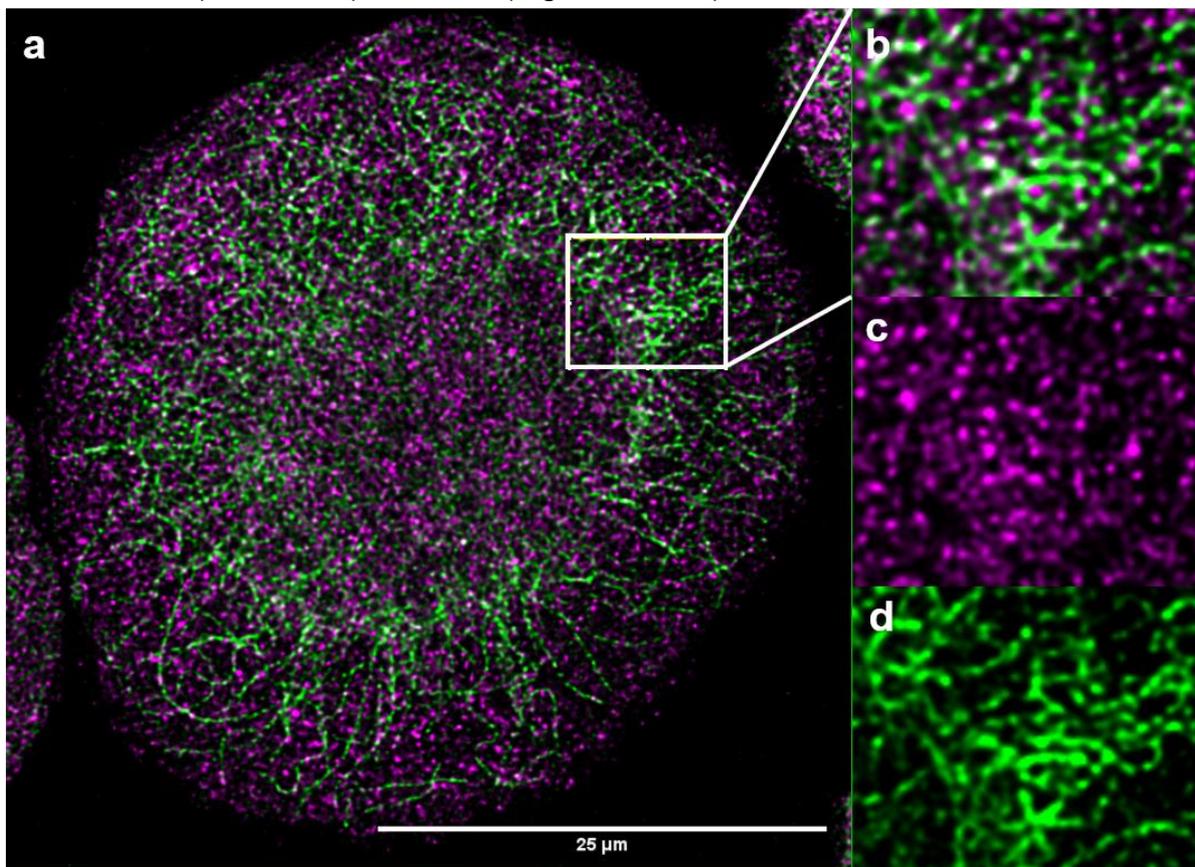

Figure 4.1.3.5: M0 monocyte derived macrophages deconvoluted Tubulin (green), VISTA D1L2G (magenta) and Dapi (blue) staining (a). Single channels of the section (b-d).

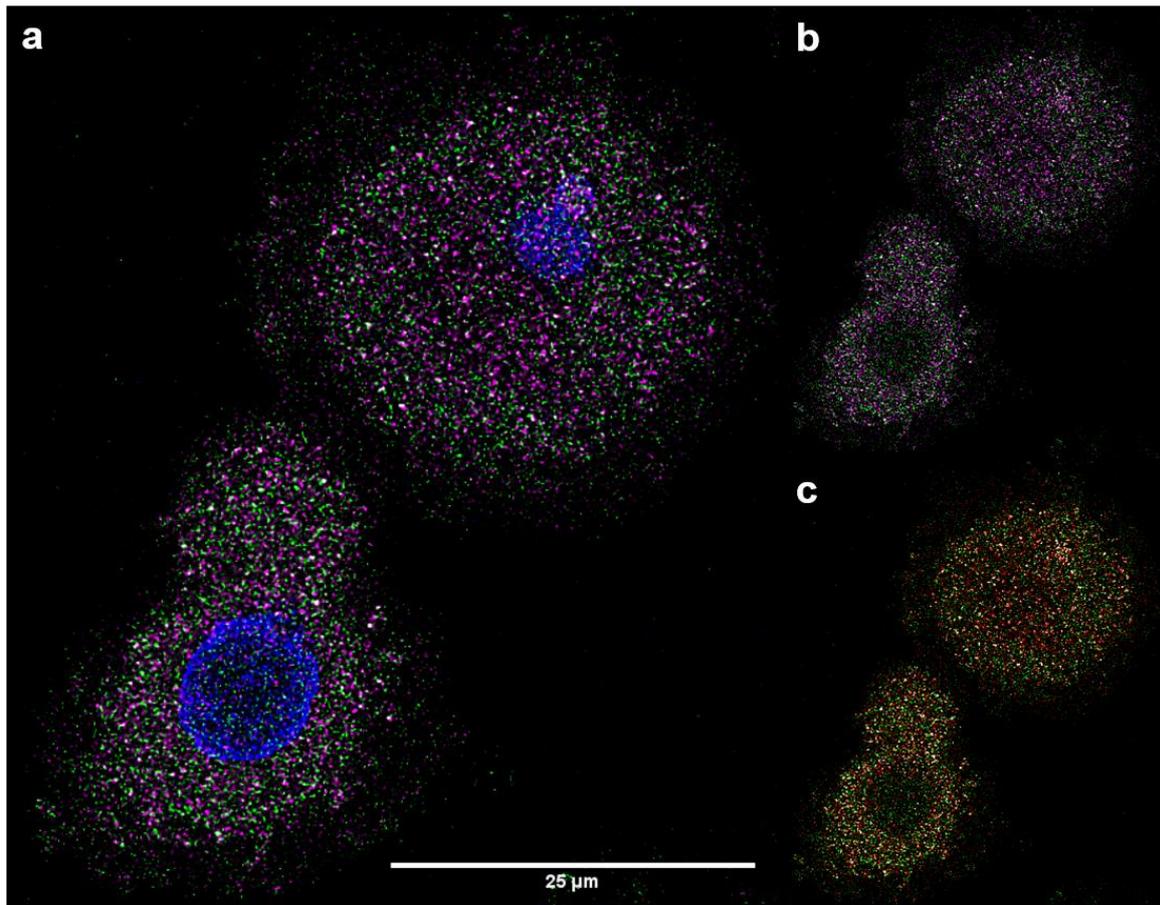

Figure 4.1.3.6: M2c monocyte derived macrophages deconvoluted Transferrin receptor (CD71) (magenta), VISTA N12 (green) and Dapi (blue) staining (a), without Dapi (b), colocalizing pixel (c, Rtotal: 0,47)

Vesicular VISTA in T-cells

We further investigated whether VISTA is expressed in vesicles in T-cells as well. VISTA staining of Jurkat cells also showed a dot-like vesicular pattern, which we observed with all anti-VISTA antibodies. The Jurkat T-cell line was used for the colocalization analysis of VISTA with the same three vesicle markers that were used before. Figure 4.1.3.7 revealed that all three marker proteins colocalized with VISTA. We also isolated vesicles from Jurkat cells and confirmed presence of VISTA in these fractions by probing fractions via Western blotting (not shown).

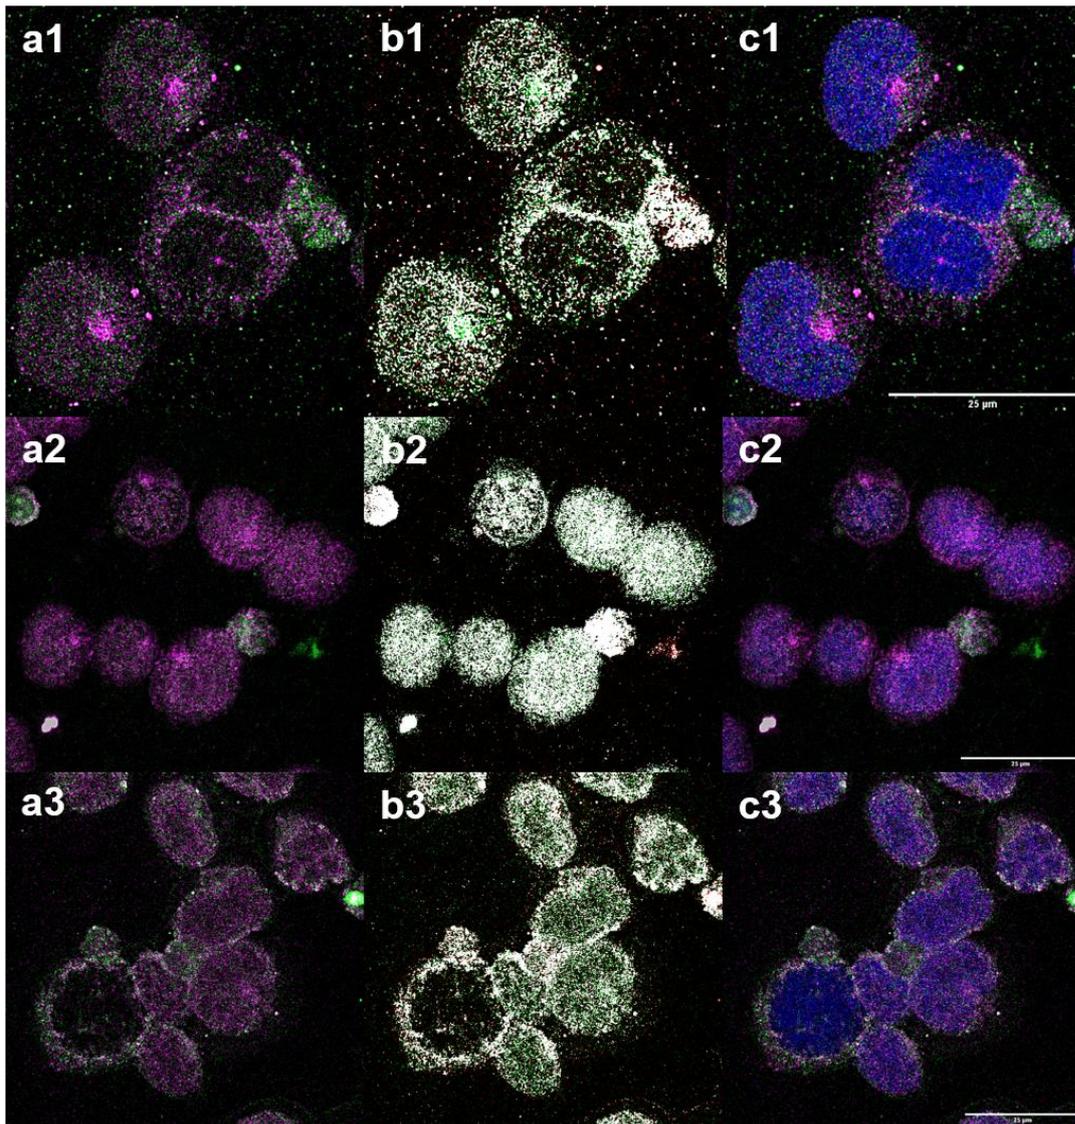

Figure 4.1.3.7: Jurkat cells deconvoluted VISTA N12 (magenta), vesicle marker (green) and Dapi (blue) (column c) staining, without Dapi (column a) and corresponding colocalizing pixel (column b). Vesicle marker Transferrin receptor (CD71) in row 1 (Rtotal: 0,259, flipped horizontal: 14,16 %, flipped vertical: no correlation found), vesicle marker Perforin in row 2 (Rtotal: 0,463, flipped horizontal: 0,75 %, flipped vertical: 25,84 %) and vesicle marker Snap-25 in row 3 (Rtotal: 0,341, flipped horizontal: 14,24 %, flipped vertical: no correlation found).

Vesicular VISTA-GFP in monocytic cell lines

To exclude or minimize non-specific antibody cross reactivity, VISTA-GFP overexpressing celllines of the monocytic celllines THP-1 and HL-60 were produced. The VISTA-GFP fusion protein was visible in a dot-like vesicular pattern in these cell lines monitored by GFP fluorescence emission (Figure 4.1.3.8). We confirmed colocalization with vesicle markers as in the control studies described above. Furthermore, isolated vesicles from the cytosol of HL-60 VISTA-GFP (Figure 4.1.3.9) and THP-1 VISTA-GFP (not shown) cells showed strong green GFP fluorescence and were positive for the vesicle marker Snap-25. Vesicles were isolated from the sucrose gradient and showed the expected size of about 1 μm .

Isolated vesicles were also used for a Western blot analysis (Figure 4.1.3.10). All three fractions of the sucrose gradient (45%, 35% and 25 % (w/w) sucrose) were compared

for both cell lines HL-60, an empty vector control (EV) and HL-60 VISTA-GFP. The HL-60 VISTA-GFP cells showed a band of the VISTA-GFP fusion protein at around 90 kDa (expected size is 64 kDa, but glycosylated VISTA-GFP displays a shift in electrophoretic mobility) at 25 % (w/w) sucrose, whereas the HL-60 EV cells showed no VISTA or GFP signal in the vesicle fractions. HL-60 VISTA-GFP cells were positive for VISTA (a) as well as for GFP (b). Protein amounts loaded on the gel were identical for HL-60 EV and HL-60 VISTA by probing the presence of Snap-25 resulting in identical staining intensity in both lanes (protein band slightly above the 28 kDa standard in Figure 4.1.3.10 c). The THP-1 cell lines showed similar results, which are not shown here.

We conclude that VISTA is expressed in vesicles and therefore resembles CTLA-4 expression.

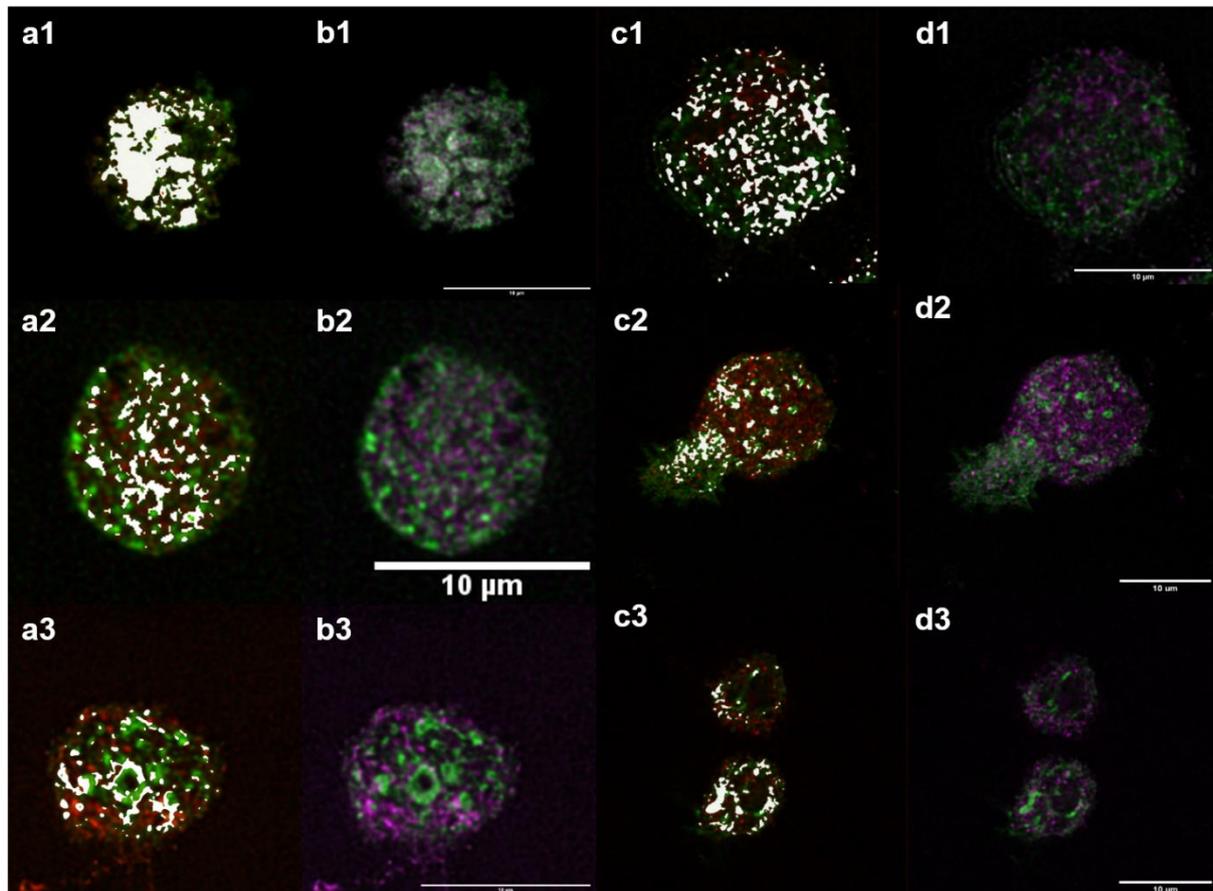

Figure 4.1.3.8: HL-60 VISTA-GFP cellline deconvoluted and vesicle marker (magenta) staining (column b) and corresponding colocalizing pixel (column a). THP-1 VISTA-GFP cellline deconvoluted and vesicle marker (magenta) staining (column d) and corresponding colocalizing pixel (column c). Vesicle marker Transferrin receptor (CD71) in row 1 (HL-60: Rtotal: 0,891, flipped horizontal: no correlation found, flipped vertical: 52,96 %; THP-1: Rtotal: 0,575, flipped horizontal: 40,09 %, flipped vertical: 4,43 %), vesicle marker Perforin in row 2 (HL-60: Rtotal: 0,738, flipped horizontal: 21,95 %, flipped vertical: no correlation found; THP-1: Rtotal: 0,675, flipped horizontal: 43,11 %, flipped vertical: no correlation found) and vesicle marker Snap-25 in row 3 (HL-60: Rtotal: 0,584, flipped horizontal: 47,44 %, flipped vertical: no correlation found; THP-1: Rtotal: 0,707, flipped horizontal: 30,02 %, flipped vertical: no correlation found)

VISTA in nuclei

While investigating the VISTA expression in different cell fractions, the staining of VISTA in the nucleus became obvious. VISTA staining appeared in a ring around the nucleus probably bound to nucleus pores but was also visible inside the nucleus (Figure 4.1.3.11 a). This staining pattern was observed with all three VISTA antibodies (not all shown) (Clones N12, S14 and D1L2G) in deconvoluted confocal pictures of murine BMDMs (Figure 4.1.3.11 a) and in the Jurkat cell line (not shown). When we tested nucleus expression of VISTA by Western Blot analysis using Jurkat cells, the nucleus fraction showed less VISTA signal compared to the pellet and organelles fraction, but a visible band at around 37 kDa (not shown). The results were further confirmed by localizing VISTA-GFP in the nucleus of HL-60 VISTA-GFP (Figure 4.1.3.11 b) and THP-1 VISTA-GFP (Figure 4.1.3.11 c) cells.

Isolated nuclei of THP-1 VISTA-GFP cells show a strong green fluorescence whereas the isolated nuclei of THP-1 EV did not show any green fluorescent signal (Figure 4.1.3.12). The corresponding blots of the pellet, nuclei and organelles fractions showed a strong band at 90 kDa for VISTA-GFP (see also above) in the THP-1 VISTA-GFP cell line. This band was positive for VISTA (Figure 4.1.3.13 a) as well as for GFP (Figure 4.1.3.13 b). The THP-1 EV cell line did only show a weak GFP signal in the organelles fraction (Figure 4.1.3.13 b) but no VISTA signal (Figure 4.1.3.13 a). We concentrated the nuclei and organelles fraction (two times more than the pellet fraction) to increase the signal. However, the pellet fraction did not enter the gel completely leading to an intense signal at the top of the gel. Thus, VISTA presence seemed more abundant in the pellet fraction and weaker in the nuclei fraction.

The nucleus expression of VISTA seemed surprising, since the amino acid sequence of VISTA does not contain any typical nucleus import motif. However, the same property and nucleus expression is known for PD-L1 (Ghebeh et al. 2010) which is closely related to VISTA (Deng et al. 2016; Lines et al. 2014a; Wang et al. 2014; Baksh und Weber 2015; Lines et al. 2014b). The nucleus expression of VISTA was also observed by (Thul et al. 2017) with the VISTA antibody by Sigma-Aldrich ([Atlas Antibodies Cat#HPA007968, RRID:AB_1845518](#)) which also supports our results. Further investigations should also concentrate on possible interaction partners like transcription factors of VISTA in the nucleus.

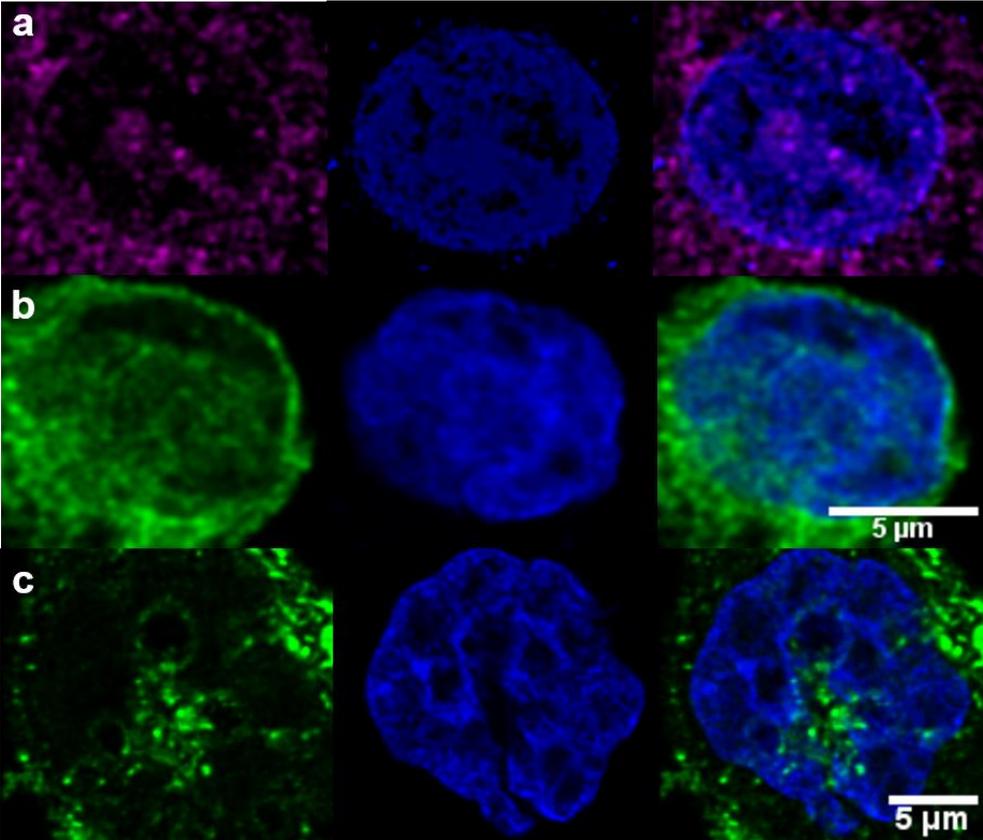

Figure: 4.1.3.11: Deconvoluted BMDM nucleus (a) with VISTA S14 (magenta) and Dapi (blue) nucleus staining and deconvoluted HL-60 VISTA-GFP (b) and THP-1 VISTA-GFP (c) cells with Dapi (blue) nucleus staining

VISTA in exosomes

Due to the presence of VISTA in vesicles we hypothesized, that VISTA might be secreted in exosomes. To investigate this hypothesis further we isolated exosomes after three days being in FCS-free cell culture from the extracellular medium of HL-60 VISTA-GFP cells and THP-1 VISTA-GFP cells. We compared the content of these preparations to the extracellular medium of HL-60 EV and THP-1 EV cells after three days being in FCS-free cell culture. Isolated exosomes were identified in IHC staining with the exosome marker CD63 in magenta (appendix Figure 7.2.8 and 7.2.9). Since exosomes are small structures of a few nm up to 1 μ m, any staining produces high background. Nevertheless, we detected GFP-positive exosomes derived from HL-60 VISTA-GFP and THP-1 VISTA-GFP cells. However, not all exosomes are positive for VISTA, but especially larger exosomes showed a GFP signal.

To confirm the results of VISTA expression in exosomes we performed a Western Blot analysis of the extracellular medium and the isolated exosomes (Figure 4.1.3.14). Isolated exosomes from the extracellular medium of HL-60 VISTA-GFP cells (Figure 4.1.3.14 a) gave a strong VISTA signal at around 90 kDa (as expected see above). This band was also positive for GFP (Figure 4.1.3.14 b). We also detected in the exosome fraction a band for the exosome marker CD63 at around 30 kDa (Figure 4.1.3.14 c) to confirm that our isolation for exosomes was successful.

VISTA is also secreted in exosomes in primary murine BMDMs (Figure 4.1.3.14 d). The isolated exosomes showed a strong VISTA band at 40 kDa (as expected see above).

While there are indications of the extracellular VISTA domain to be shedded and released in the medium to operate as a signal molecule (Sakr et al. 2010), there were no indications yet of VISTA being present in exosomes. This finding shows a complete

new possible pathway of cell-cell-communication via VISTA in the tumor microenvironment in secreted exosomes and should be investigated further.

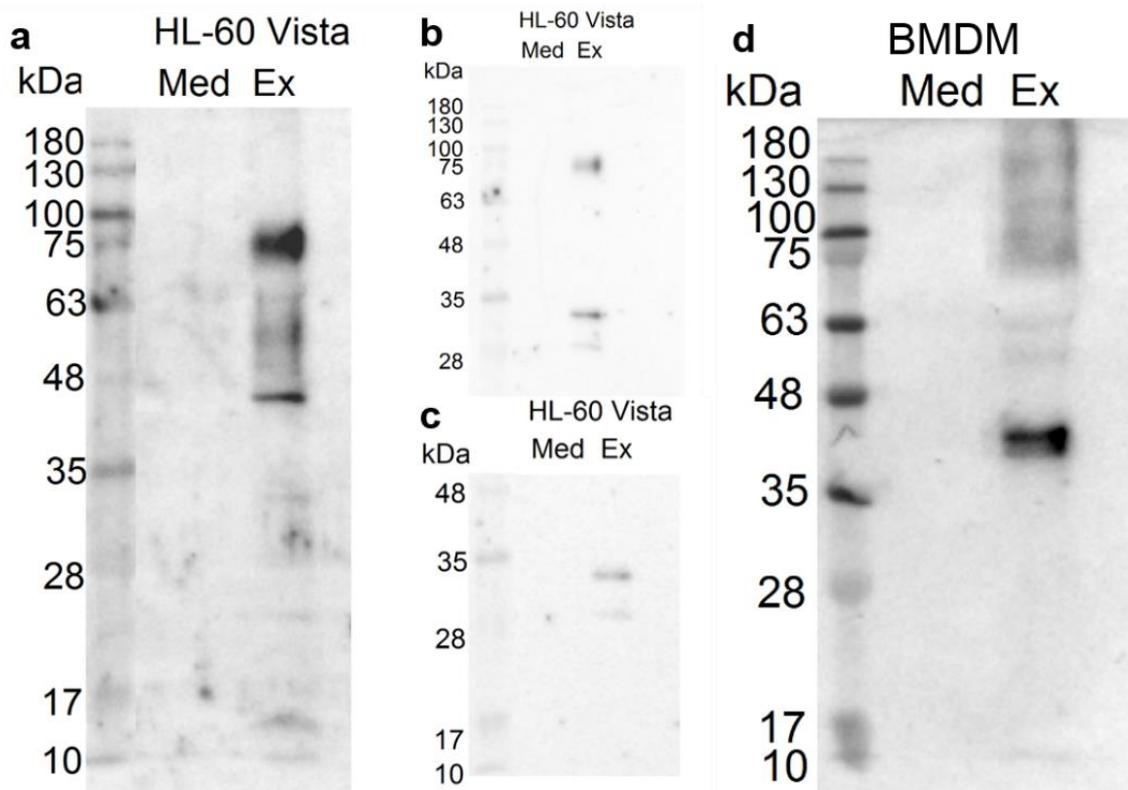

Figure 4.1.3.14: Western Blots of medium and isolated exosomes of HL-60 VISTA-GFP cells. 4.2 Effect of stimulation

4.2.1 Immunogenic stimulation

To observe the effect of an immunogenic stimulus on the VISTA expression, lipopolysaccharide (LPS) was chosen as a stimulus. The success of stimulation of BMDMs was measured by IL-6 Elisa (Figure 4.2.1.1). Antigen Presenting Cells secrete the cytokine IL-6 after activation and immunological stimulation.

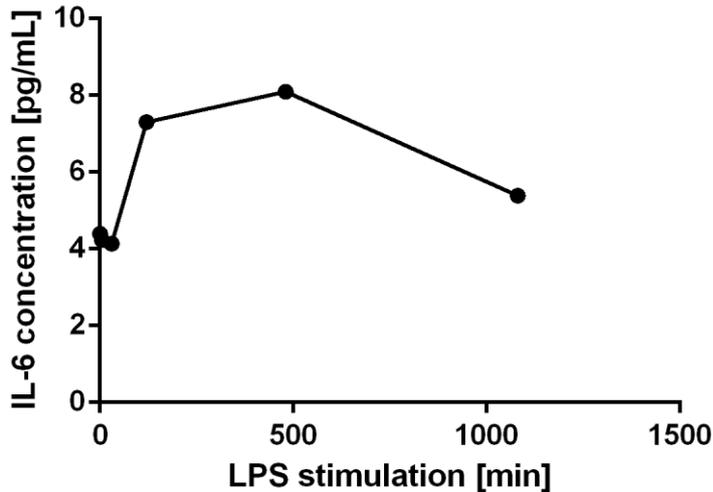

Figure 4.2.1.1: IL-6 Elisa of BMDM medium during LPS stimulation, concentration average of three fluorescent determinations

After stimulation with LPS (5 $\mu\text{g}/\text{mL}$), BMDMs did not secrete any additional IL-6 within the first 30 min. There was a basal activity and IL-6 concentration of about 4,4 pg/mL in the medium. After two hours of LPS stimulation, BMDMs already secreted nearly twice as much IL-6 in the medium. BMDMs were fully activated after around 8 hours which is displayed by the maximum of IL-6 concentration with 8,1 pg/mL after 8 hours. A sustaining stimulation over 18 hours did not led to higher IL-6 concentrations. After 18 hours the IL-6 concentration was decreased to 5,4 pg/mL which was higher than naive status but also not at the maximum anymore.

The LPS stimulation led to the expected activation curve and IL-6 secretion of BMDMs. Therefore, the LPS stimulation was assumed as successful and sufficient for further stimulation kinetics.

Unstimulated BMDMs (Figure 4.2.1.2 a) showed a strong and dot-like VISTA staining pattern with nearly no VISTA in the nucleus. After stimulation of a few minutes with LPS (b) the staining got weaker and more diffuse (b). This was probably due to the release of VISTA vesicles to the cell surface. Stainings on the cell surface were less concentrated compared to vesicle staining and appeared weaker and more diffuse. Stimulation of around 30 min (c) led to a focused VISTA staining of the nucleus (bright areas within the cell body). This pattern was gone after a few hours of LPS stimulation (d) and became a strong vesicular staining in the whole body. The VISTA fluorescence was often stronger after 18 h LPS stimulation, compared to the native state.

This staining pattern appeared consistently but depending on the cells with a shifted kinetic. For example, nucleus staining sometimes appeared stronger after 2 h than after 30 min already.

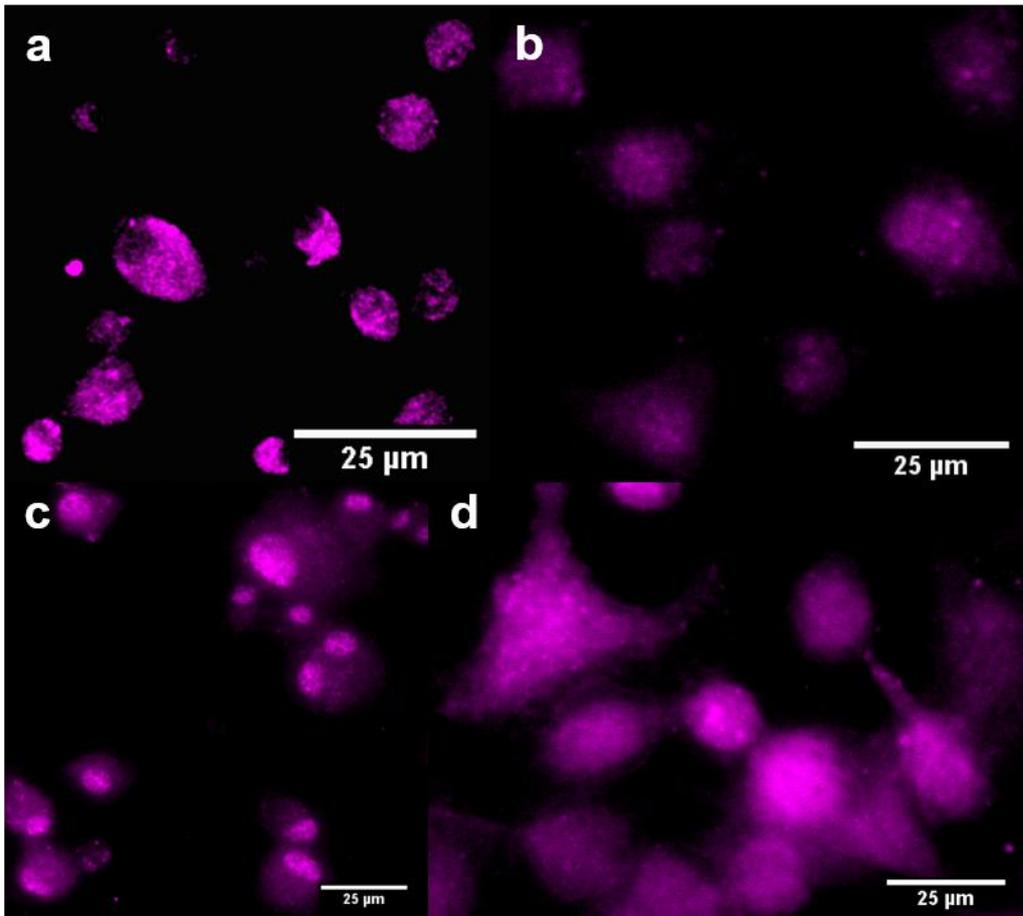

Figure 4.2.1.2: VISTA S14 staining (magenta) of BMDMs during LPS stimulation (a) native, b) 2 min LPS, c) 30 min LPS d) 18 hours)

First the hypothesis of released vesicles within the first few minutes of LPS stimulation should be investigated, followed by investigating the effects of LPS stimulation on nuclear VISTA expression.

Effect of LPS stimulation on vesicular expression

To check whether the observed diffuse staining within the first few minutes of LPS stimulation was due to a release of vesicles, the particle analysis (3.2.26) was used in BMDMs. For that the numbers of vesicles positive for VISTA and positive for a vesicle marker were compared to the double positive vesicles (Figure 4.2.1.3 and 4.2.1.4).

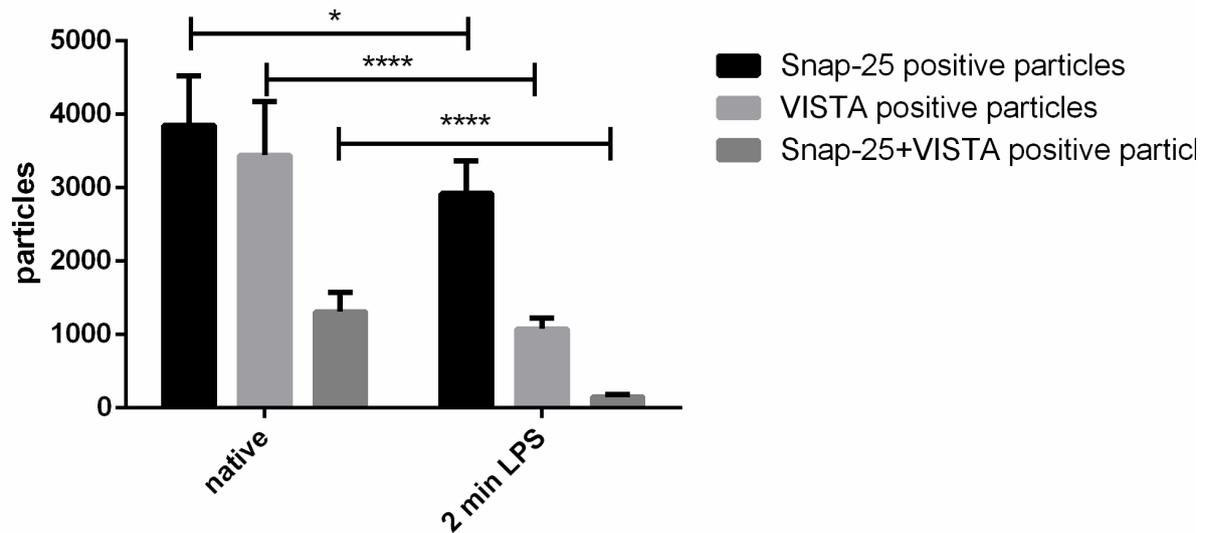

Figure 4.2.1.3: Particle analysis of VISTA and Snap-25 in BMDMs, n=1 in quadruplets

For the vesicle marker Snap-25 we could observe a clear release of vesicles, due to 2 min LPS stimulation (Figure 4.2.1.3). The vesicles which were positive for Snap-25 and VISTA decreased highly significant (1311,33 to 152,25 particles) due to LPS stimulation of 2 minutes. The question is whether this decrease was due to release of VISTA positive vesicles or due to loss of Snap-25 positive vesicles. While the Snap-25 positive vesicles only decreased significantly (3853,67 to 2921 particles), the VISTA positive vesicles showed a highly significant drop of 3444-67 to 1077,25 particles. With that we could assume, that the loss of double positive vesicles is due to the release of VISTA positive vesicles after LPS stimulation.

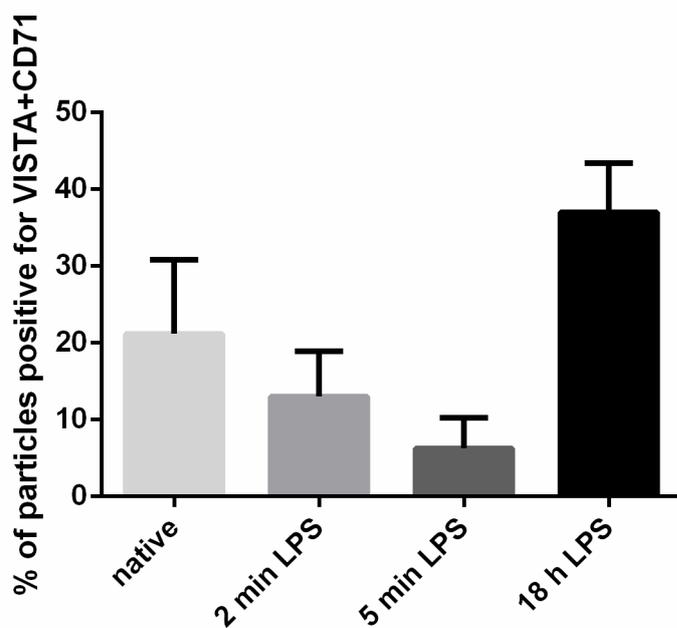

Figure 4.2.1.4: Particle analysis of VISTA and the Transferrin receptor (CD71) in BMDMs, n=2 in triplicates

We checked the progression of double positive vesicles for VISTA and the vesicle marker Transferrin receptor (CD71) (Figure 4.2.1.4) and observed a decrease for the first few minutes of LPS stimulation. While in the native state 21,2 % of all vesicles were positive for VISTA and CD71, this amount decreased to 13 % after 2 min and 6,3 % after 5 min LPS stimulus. This finding was consistent with the vesicle marker Snap-25 (Figure 4.2.1.3).

In the stainings of BMDMs we could often observe a stronger VISTA fluorescence for cells which were stimulated with LPS for 18 h (Figure 4.2.1.2). Also, the percentage of double positive vesicles was higher after 18 h of stimulation (37 %) for Transferrin receptor. Since the double positive particles followed the VISTA positive particles (Figure 4.2.1.3) we can assume, that a sustaining stimulation with LPS for 18 hours, led to a higher amount of VISTA vesicles in Antigen Presenting Cells.

This hypothesis could be confirmed by the numbers of VISTA positive particles/cell (Figure 4.2.1.5) after LPS stimulation. 5 min of LPS stimulation led to a significant drop of VISTA positive vesicles per cell (native 47,65, 5 min LPS 34,23 particles/cell). The stimulation with LPS for 30 – 120 min showed a very high standard deviation because some cells seemed to be highly responsive towards the LPS stimulus, leading to a highly increased number of VISTA positive particles, while many cells did not respond that strongly. But observing the mean (83,75 after 30 min, 108,68 after 120 min) of the samples, we could see a continuous increase of VISTA positive particles/cell, which became significant after 480 min (114,41 particles/cell) of LPS stimulation. This increased level of VISTA positive particles/cell stayed stable also after 18 hours of LPS stimulation (94,95 particles/cell)

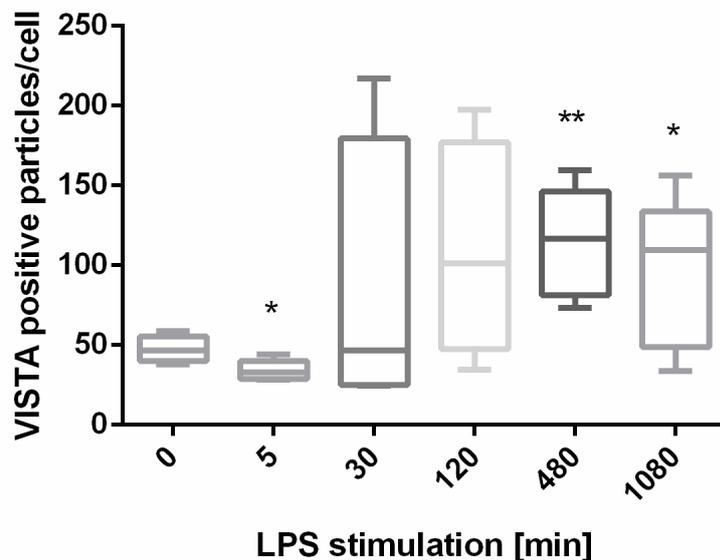

Figure 4.2.1.5: VISTA positive particles/cell in BMDMs during LPS stimulation, significance to the native BMDM sample is indicated, n=1 in quintuplets

So, via particle analysis we could assume that VISTA positive vesicles were released shortly after an immunogenic stimulus. Sustaining immunogenic stimulation led to the production of more VISTA positive vesicles.

Effect on the nuclear expression

The VISTA staining of BMDMs after LPS stimulation revealed a high increase of nuclear VISTA expression after 30-120 min. This aspect should be confirmed now further.

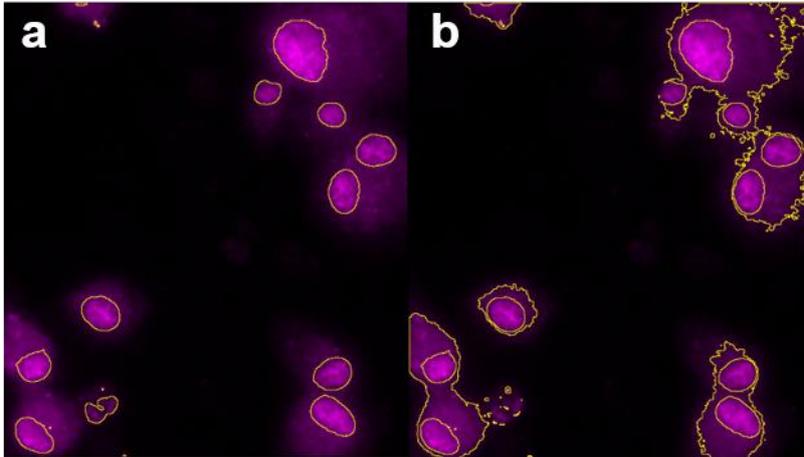

Figure 4.2.1.6: Visualization of analysis example for a) nucleus and b) cytosol fluorescence

To quantify the different amounts of VISTA in the cytosol compared to the nucleus the VISTA fluorescence was measured in the different compartments. The nuclei were stained with Dapi and a matching threshold for complete nuclei without background was defined (Figure 4.2.1.6 a). The cell bodies were defined by VISTA staining or the membrane marker CD11b. The threshold was adapted for intact outer membrane of the cells. To define the cytosol the nuclei were excluded from the cell bodies (b). To visualize the translocation of VISTA to the nucleus due to LPS stimulation the ratio of nuclei/cytosol fluorescence was quantified (Figure 4.2.1.7).

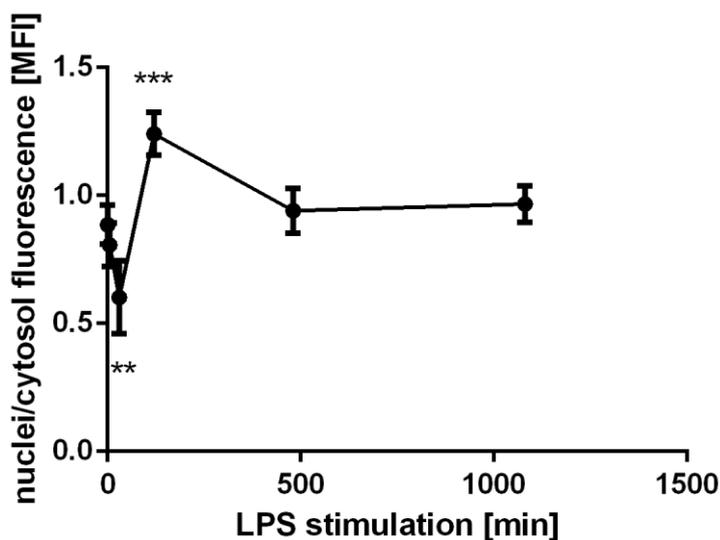

Figure 4.2.1.7: Example experiment: nuclei/cytosol fluorescence during LPS stimulation of BMDMs, significance to the native BMDM sample is indicated, n=1 in quintuplets

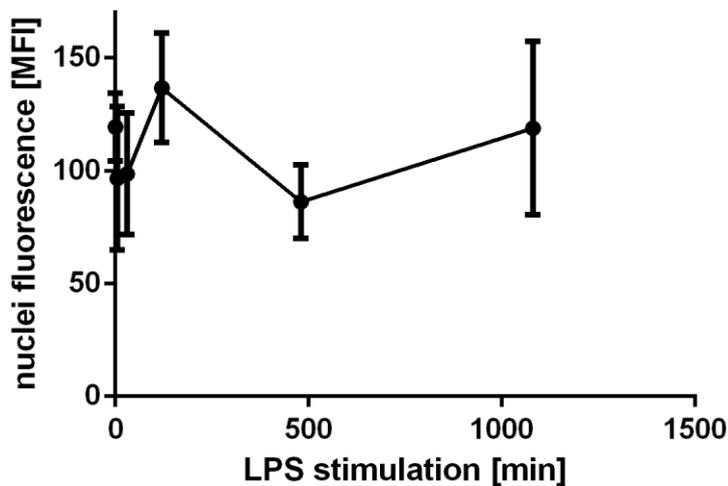

Figure 4.2.1.8: Nuclei fluorescence during LPS stimulation of BMDMs of the example experiment, n=1 in quintuplets

Figure 4.2.1.7 showed one example experiment of the nuclei/fluorescence analysis of BMDMs. Without LPS stimulation, the VISTA was nearly equally distributed with a little less staining in the nucleus compared to the cytosol (ratio 0,886). After LPS stimulation the VISTA signal shifted towards the cytosol (ratio after 5 min 0,81, ratio after 30 min 0,6) with a very significant decrease after 30 min compared to the native state. Sustaining stimulation with LPS led to stronger VISTA signal in the nuclei compared to cytosol with a maximum after 120 min (ratio 1,24). This increase in nuclear VISTA expression was highly significant compared to the native state. Longer stimulations with LPS led to balanced distribution of VISTA staining between cytosol nuclei (ratio 480 min: 0,94, 1080 min: 0,967). As already mentioned, the kinetic of the strong nucleus staining shifted and appeared between 30 min to 120 min. So, the graph of Figure 4.2.1.7 could change its peak between 30 to 120 min with every experiment, but the pattern remained the same.

The values of Figure 4.2.1.8 correspond to the ratio of Figure 4.2.1.7. Both graphs showed nearly the same curve shape, so we could conclude, that the shape of the graph in 4.2.1.7 is due to the VISTA nucleus fluorescence (Figure 4.2.1.8). But you could see an increase in nuclear fluorescence for 1080 min LPS stimulation, which was not observable in the nuclei/cytosol fluorescence ratio, indicating the increased overall VISTA fluorescence in cytosol and nucleus after sustaining LPS stimulation.

Therefore, we could conclude for BMDMs, that the stimulation with LPS led to a short drop of nucleus VISTA expression with increased VISTA expression in the cell body, followed by a transient increased VISTA nucleus expression for up to two hours. After 8 hours the VISTA expression was distributed equally within the cell, but the overall VISTA expression increased. The nuclear translocalization of VISTA was faster than the IL-6 secretion (4.2.1.1). While the nucleus expression was at its maximum between 30-120 min and recovered after 480 min, the highest IL-6 secretion was after 480 min LPS stimulation.

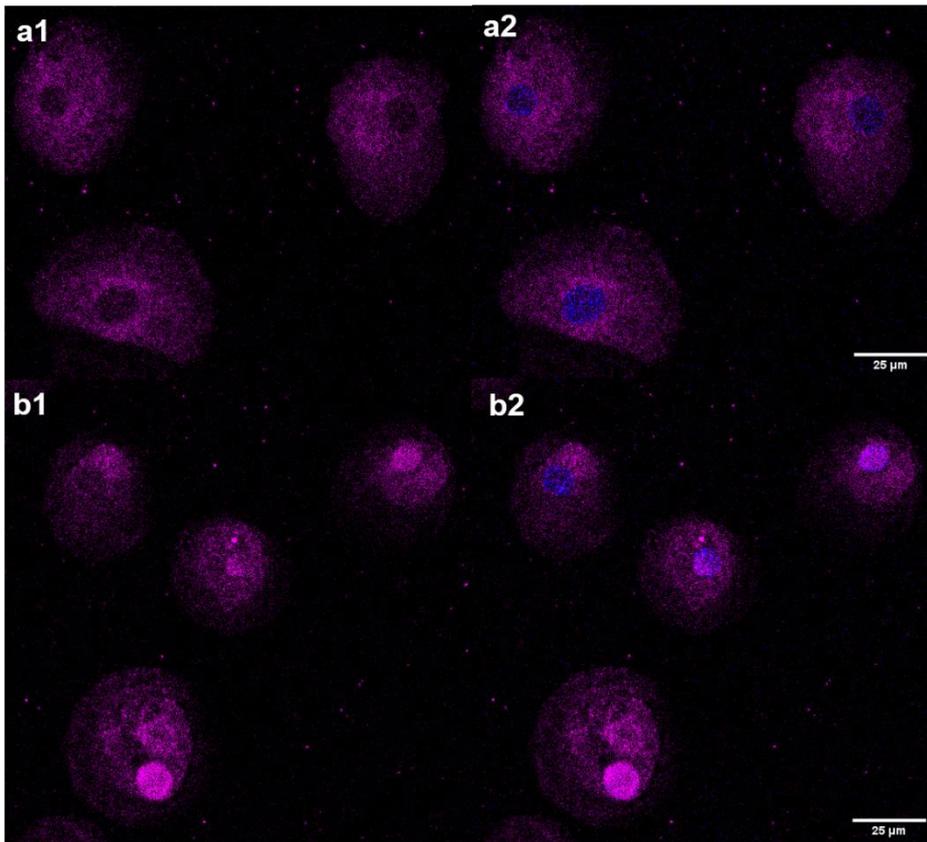

Figure 4.2.1.9: Confocal VISTA D1L2G (magenta) and Dapi nucleus (blue) staining of human monocyte derived macrophages during LPS stimulation kinetic (a) native, b) 30 min LPS

We could observe the same staining pattern in primary human monocyte derived macrophages (Figure 4.2.1.9) like in BMDMs (Figure 4.2.1.2). Native monocyte derived macrophages did not show VISTA expression in the nucleus, whereas 30 min LPS stimulation led to a VISTA signal, colocalizing with the nucleus marker Dapi.

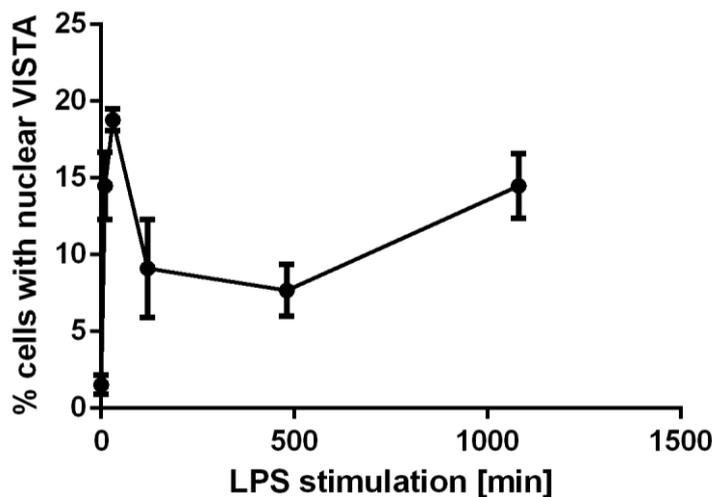

Figure 4.2.1.10: Example experiment: percentage of monocyte derived macrophages with nuclear VISTA signal due to LPS stimulation, n=1 in quadruplets

Native human monocyte derived macrophages did barely show any VISTA expression in the nucleus (Figure 4.2.1.10, 1,5 %). Stimulation with LPS led to an increase of cells with nuclear VISTA with a maximum after 30 min (18,8 %) stimulation. The sustaining

LPS stimulation for 2-8 hours led to a drop of nuclear VISTA (480 min 7,7 %) which increased again after long-term stimulation for 18 h (14,5 %).

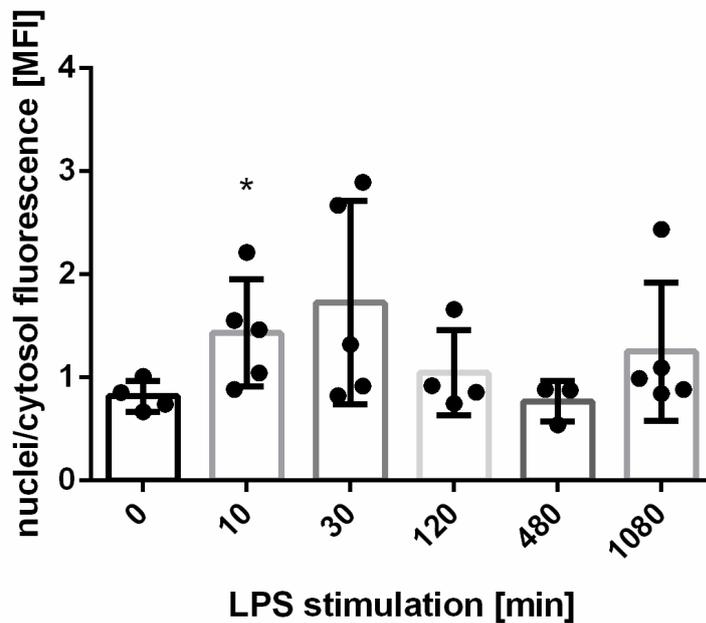

Figure 4.2.1.11: Example experiment: nuclei/cytosol fluorescence during LPS stimulation of human primary monocyte derived macrophages, significance to the native monocyte derived macrophage sample is indicated, n=1 in quadruplets

Human primary monocyte derived macrophages showed overall a quite low percentage of nuclear VISTA positive cells (Figure 4.2.1.10) leading to nuclei/cytosol fluorescence with a high standard deviation (Figure 4.2.1.11). Nevertheless, the percentage of cells with VISTA signal in the nucleus exactly fitted the nuclei/cytosol fluorescence pattern. Compared to BMDMs, monocyte derived macrophages did not show a significant decrease in nuclear VISTA expression for a few minutes, but only a significant increase in nuclear VISTA expression after 10-30 min LPS stimulation. This decreased afterwards for several hours. Sustaining LPS stimulation for 1080 min again led to a small increase in the fluorescence ratio towards to nuclear expression.

The analysis in Figure 4.2.1.10 and 4.2.1.11 were only based IHC stainings. But to investigate the expression of VISTA, it was important to measure the VISTA RNA as well. For that, a qRT-PCR of VISTA was performed in monocyte derived macrophages (Figure 4.2.1.12).

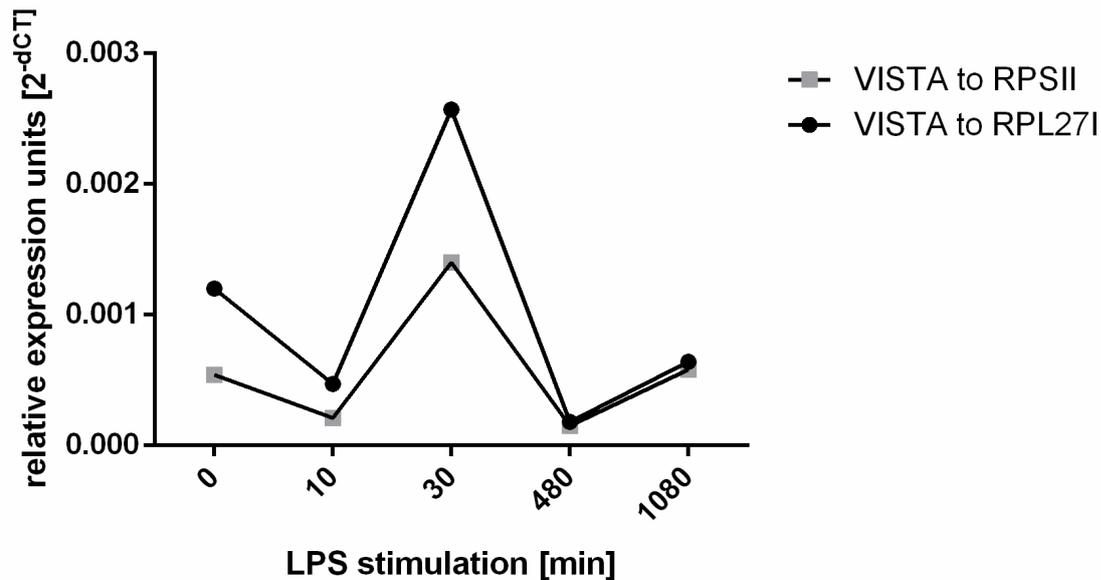

Figure 4.2.1.12: qRT-PCR of VISTA in LPS stimulated human monocyte derived macrophages, n=1 in triplicates

Like described in 4.1.2, both reference genes RPSII and RPL27 for VISTA expression (Figure 4.2.1.12), showed the same curve shape but a difference in VISTA amount. But to classify the results, the curve shape was sufficient. The RNA amount of VISTA basically followed the pattern of VISTA nuclear staining in BMDMs and monocyte derived macrophages. After 10 min stimulation, VISTA amount dropped (on 40 % compared to native state for RPSII), displaying that the existing VISTA RNA was translated into protein, without sufficient transcription to RNA to compensate the drop. After 30 min of LPS stimulation the VISTA expression was strongly increased up to 260 % (RPSII) compared to native state, displaying the highly increased transcription of VISTA. The VISTA amount dropped again after 480 min LPS stimulation on 28 % (RPSII) of the native state. Sustaining LPS stimulation for 1080 min (107 % of native state for RPSII) balances the VISTA level back to native state.

The stimulation with LPS did show an effect on the nuclear expression of VISTA in Antigen Presenting Cells, leading to a significant increase of nuclear VISTA after 30-120 min of stimulation accompanied by increased VISTA RNA levels. Over night stimulation with VISTA led to increased VISTA fluorescence caused by more VISTA positive vesicles. But production level of VISTA was comparable to the native state again after 18 h stimulation.

4.2.2 Effect of inhibitors

VISTA is a membrane protein, so the question arised how it can reach the nucleus. One hypothesis was, that the γ -secretase cuts off the intracellular domain, leading to a transport in the nucleus. The γ -secretase does not have a special recognition motif and is responsible for the cutting of many type I membrane-proteins, like VISTA (Elad et al. 2015). To test if the γ -secretase could have an impact on the nuclear translocation, the γ -secretase inhibitor N-[N-(3,5-difluorophenacetyl)-1-alanyl]-S-

phenylglycine t-butyl ester (DAPT) (10 μ M) (Kanungo et al. 2008) was incubated for 24 h. Afterwards the stimulation with LPS was performed for 30 min, to observe if the nucleus translocation of VISTA is still occurring.

In addition, it is known, that VISTA is shedded by the membrane-type-I matrix metalloprotease (MT-1 MMP) (Sakr et al. 2010). To test if the shedding is necessary for the nuclear translocalization of VISTA 20 μ M of the broad spectrum MMP and ADAM inhibitor N-[2-[2-(Hydroxyamino)-2-oxoethyl]-4-methyl-1-oxopentyl]-3-methyl-L-valyl-N-(2-aminoethyl)-L-alaninamide (TAPI-2) was incubated for 48 h (Raissi et al. 2014). Afterwards LPS was added for 30 min.

The confocal staining of human monocyte derived macrophages (Figure 4.2.2.1) showed the expected pattern for native cells (a) and after 30 min of LPS stimulation (b). The preincubation with DAPT (c) did not show any nuclear VISTA staining after 30 min of LPS stimulation. Instead the fluorescence signal in the cell body was stronger than in the other conditions and the membrane staining is more pronounced. The preincubation with TAPI-2 (d) also did not show any nuclear VISTA signal after 30 min of LPS stimulation. The staining also showed a pronounced membrane staining which was not observable in the native cells at all and a stronger VISTA fluorescence in the cell body. To confirm these stainings, the percentage of cells with VISTA staining in the nucleus was quantified (Figure 4.2.2.2).

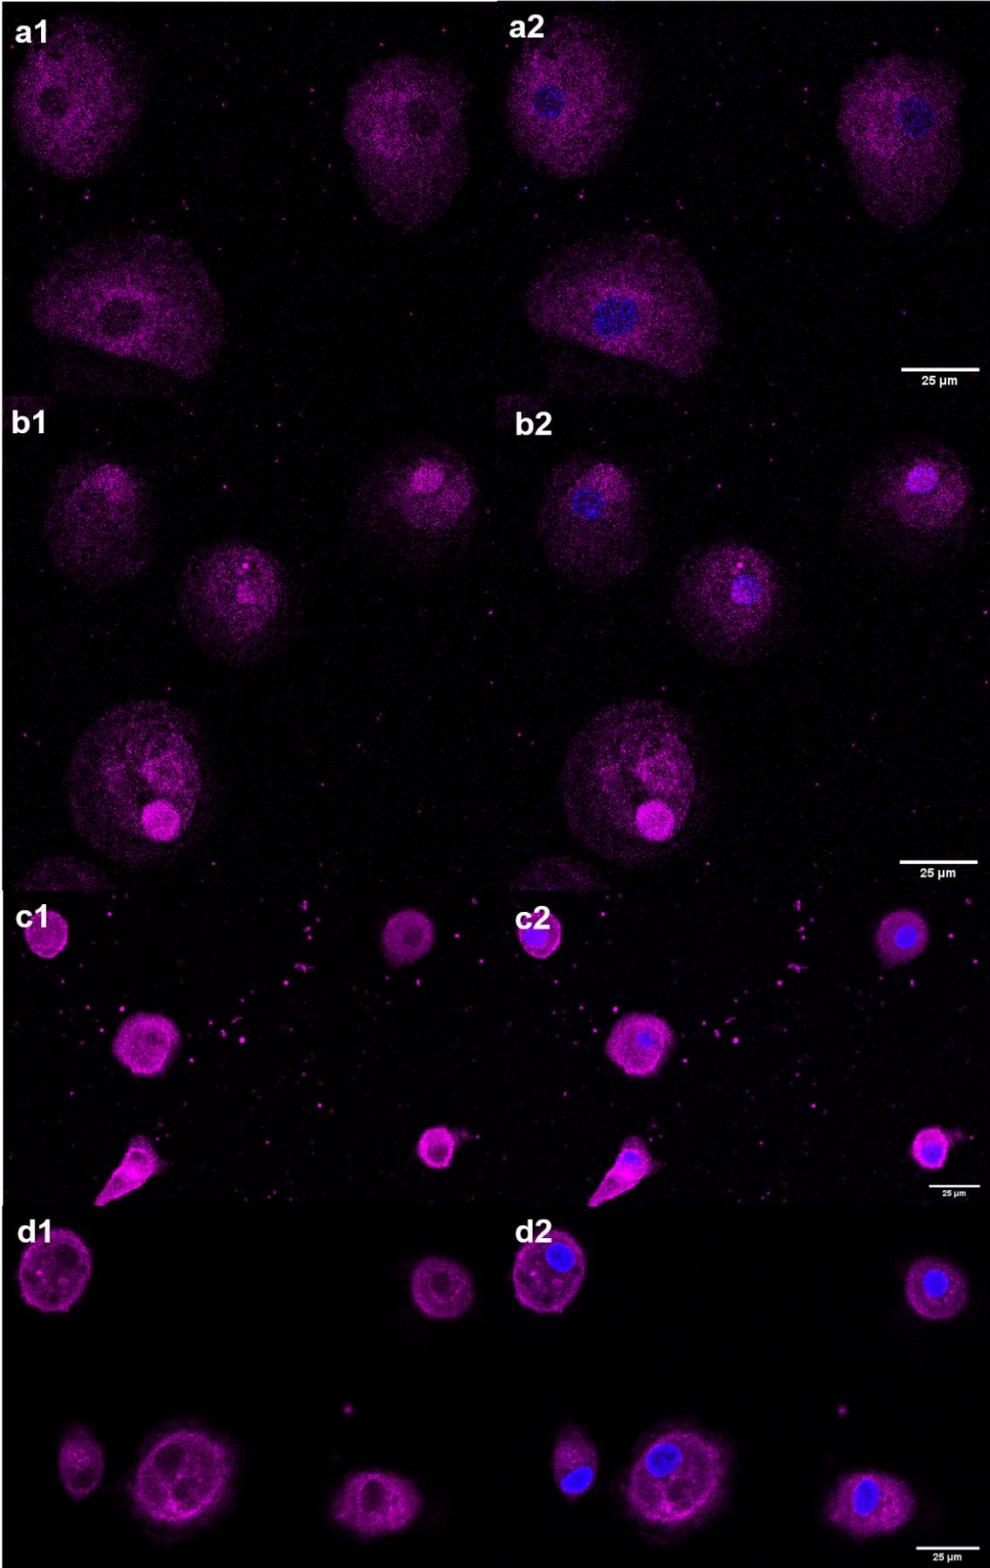

Figure 4.2.2.1: Confocal staining of VISTA D1L2G in human monocyte derived macrophages a) native, b) 30 min LPS, c) 24 h 10 μM DAPT + 30 min LPS d) 48 h 20 μM TAPI-2 + 30 min LPS

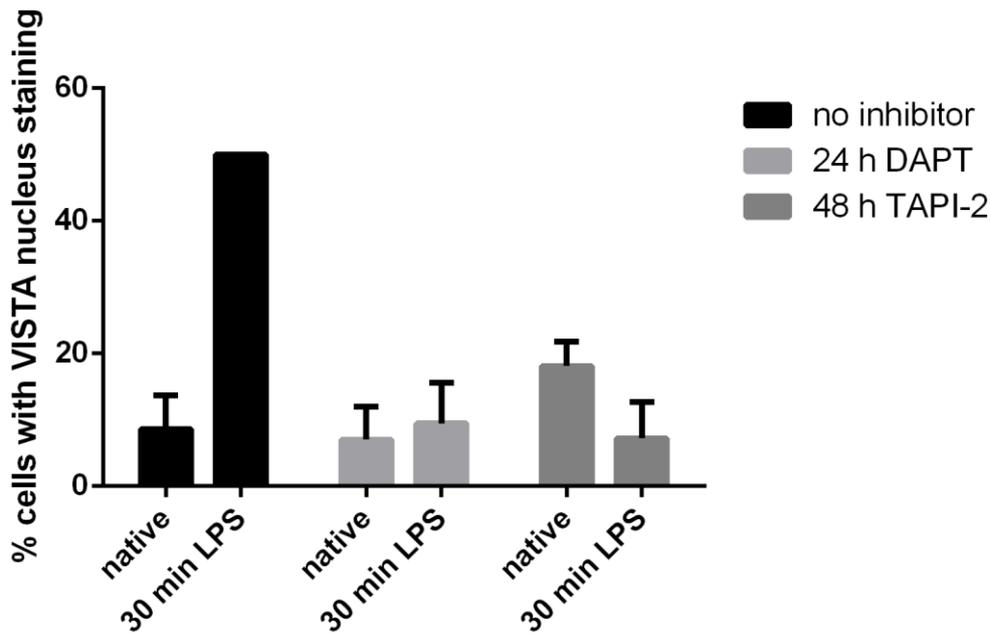

Figure 4.2.2.2: Example experiment: percentage of human monocyte derived macrophages with nuclear VISTA w/o inhibitors and LPS stimulus, standard deviation of 30 min LPS sample is 0, n=1 in triplicates

For monocyte derived macrophages without inhibitor incubation, the stimulation with LPS for 30 min, led to a strong increase in cells with nuclear VISTA from 8,6 to 50 %. But the preincubation with DAPT for 24 h inhibited this effect. The percentage of cells with nuclear VISTA stayed comparable low with 7 to 9,5 % with LPS stimulation. The preincubation for 48 h with TAPI-2 led to a quite high percentage of 18,1 % of cells with nuclear VISTA. The addition of LPS for 30 min did not led to any further increase of cells with nuclear VISTA (7,2 %), but to comparable results to the native cells without inhibitor.

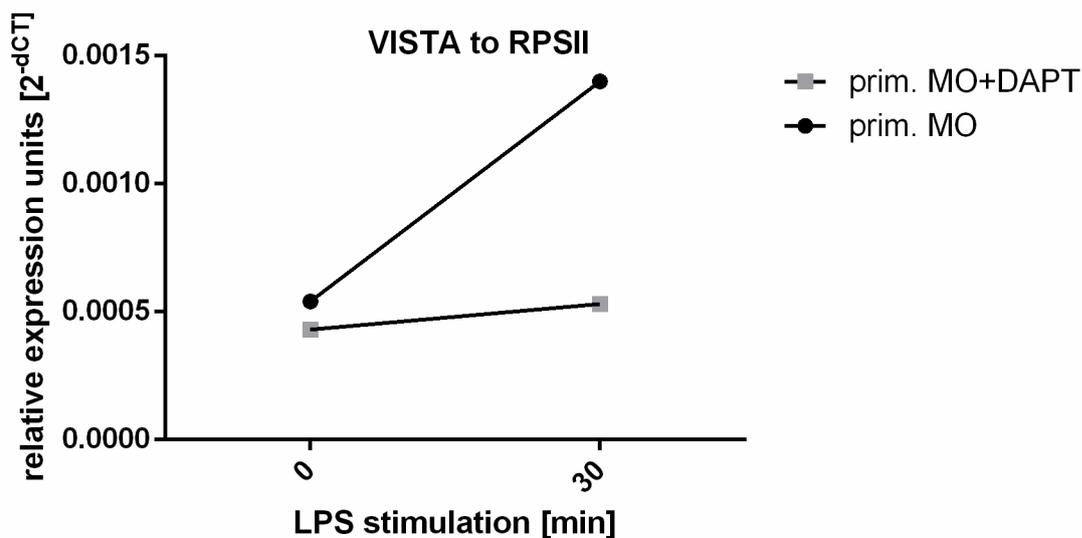

Figure 4.2.2.3: qRT-PCR of VISTA in primary monocyte derived macrophages (prim. MO) w/o DAPT and LPS stimulation, n=1 in triplicates, RPSII as reference gene

In addition to the staining, we checked for the RNA level of VISTA in monocyte derived macrophages with and without DAPT inhibitor and LPS stimulation (Figure 4.2.2.3). As already observed before, the stimulation of the primary macrophages (prim. MOs) for

30 min with LPS, led to a 2,6 times higher VISTA RNA amount compared to the native state. The preincubation with DAPT for 24 h diminished this effect and led to only a 1,2 times higher VISTA RNA amount to the native state.

Overall, the inhibition of the γ -secretase via DAPT and MMPs and ADAMs via TAPI-2 seemed to influence the nuclear VISTA expression. But to clarify if the shedding and cutting of the different VISTA domains was necessary for nuclear translocation, there are further investigations necessary.

4.2.3 Stimulation by cell density

Missing cell-cell contact, or too high cellular density is another kind of stress stimulus for cells. For nuclear PD-L1, it was observed, that lacking cell-cell-contact led to higher percentage of nuclear PD-L1 (Satelli et al. 2016). To test if this stress led to a similar translocation of VISTA like an immunogenic stimulus, BMDMs were seeded in different densities.

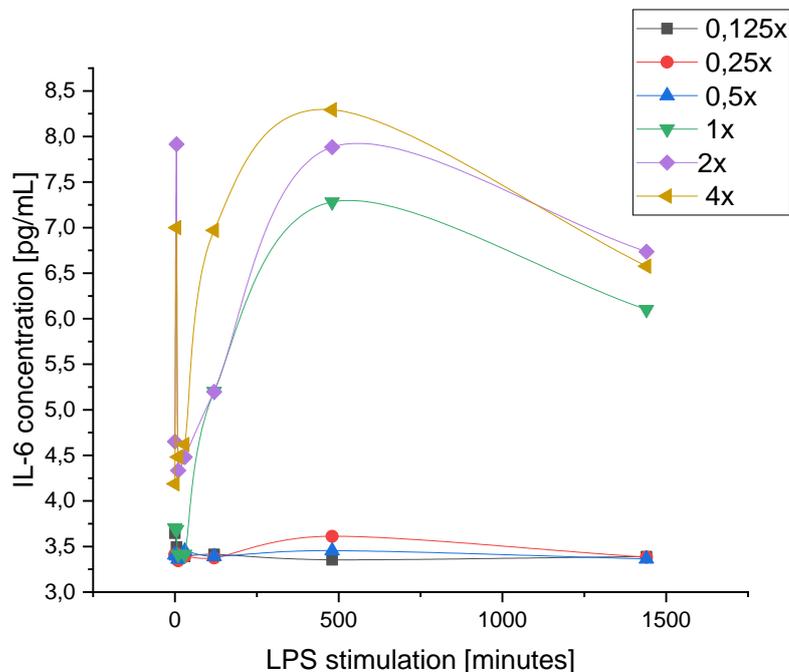

Figure 4.2.3.1: IL-6 Elisa of BMDM during LPS stimulation, seeded in different densities (Inset), n=1 in triplicates

To check if the different cell densities led to stress of BMDMs, the IL-6 concentration was measured while an LPS kinetic (Figure 4.2.3.1). The missing cell-cell contact of lower cell densities than 1x prevented the activation of BMDMs by LPS. Although after sustaining LPS stimulation for 24 hours, no IL-6 production beside the basal concentration (around 3,5 pg/mL) was observable for 0,125x, 0,25x and 0,5x cell densities. The normal cell density showed the expected pattern. Short stimulation with LPS first led to a drop of IL-6 concentration. Full activation and the highest IL-6 concentration was reached after 480 min with twice as much IL-6 than the basal state. Long-term stimulation for 24 h with LPS led to a decrease of IL-6 to 6 pg/mL.

An increased cell density of 2x or 4x led to a higher basal activity compared to 1x cell density and IL-6 concentration of ~4,5 pg/mL. LPS stimulation for 5 minutes led surprisingly to a high increase in IL-6 concentration up to 7-8 pg/mL which dropped again after 10 min stimulation back to ~4,5 pg/mL. The peak of IL-6 concentration after 480 min LPS stimulation was not much higher for 2x and 4x cell density than for normal cell density. Also, the decrease of IL-6 concentration after 24 h LPS stimulation proceeded similar to the 1x cell density. Therefore, we could conclude, that missing cell-cell-contact prevented stimulation of the cells. Whereas higher cell densities led to a little higher basal activation and IL-6 concentration but permitted a normal LPS stimulation of the cells.

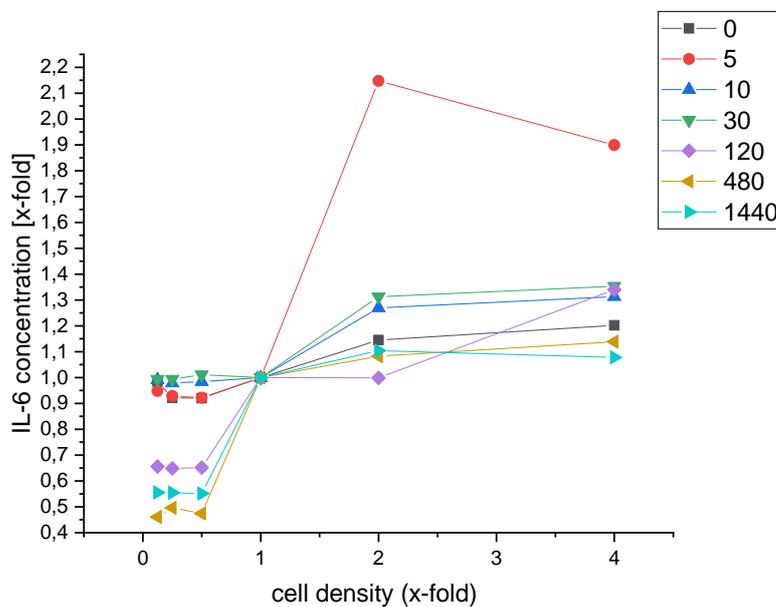

Figure 4.2.3.2: Normalized IL-6 concentration for different BMDM densities (Inset) during LPS stimulation, similar dataset like Figure 4.2.3.1, n=1 in triplicates

If you normalize all samples to the values of the normal 1x cell density (Figure 4.2.3.2) one can observe that higher cell densities only led to a 1,35 times higher IL-6 concentration as a maximum. There was only much higher activation and IL-6 concentration in the samples of 5 min LPS stimulation. But this strong activation was not stable or consistent. In addition, there was nearly no difference observable if one seeded BMDMs in 2x or 4x higher cell density. We could assume that a higher cell density did not lead to a corresponding higher activation and IL-6 concentration.

To check if the cells did still show more nuclear expression for different cell densities, we analyzed the nuclei/cytosol fluorescence for LPS kinetic on BMDMs. For lower cell densities <1x it was not possible to fix and analyze enough cells/slide so they are not part of Figure 4.2.3.3. Four times higher cell density showed for native BMDMs and 5 min LPS stimulation a highly significant lower nuclei/cytosol fluorescence. For 10 min and 30 min, neither 2x nor 4x cell density showed any significant difference to the normal cell density. So, we could assume that the slightly higher IL-6 concentration with higher cell densities after LPS stimulation, did not have a strong effect on the nuclear VISTA expression after stimulation with LPS. But higher cell densities seemed

to reduce the nuclear expression of VISTA in unstimulated and shortly stimulated BMDMs for very high cell densities.

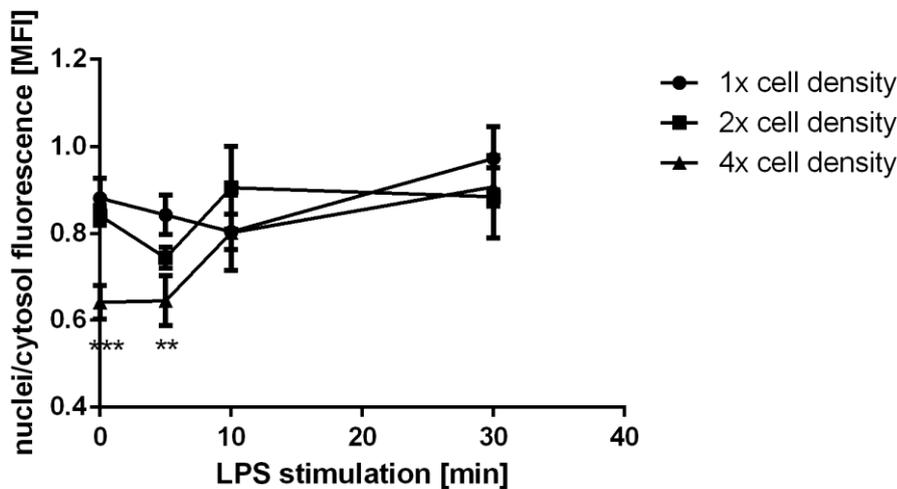

Figure 4.2.3.3: Nuclei/cytosol fluorescence of BMDM during LPS stimulation, seeded in different densities, significance to the 1x cell density BMDM sample is indicated, n=1 in triplicates

4.1 Consequences of VISTA overexpression on APCs

In the following chapter, some functional effects of VISTA overexpression on Antigen Presenting Cells should be investigated. For that, two VISTA overexpressing celllines were produced. THP-1 and HL-60 which were transfected with VISTA-GFP for a traceable overexpression of the VISTA protein. As negative controls, the corresponding empty vector (EV) cells with GFP expression or the wildtype (wt) were used. Both celllines are myeloid suspension cells but can be differentiated into macrophage-like cells with phorbol 12-myristate 13-acetate (PMA). The differentiated cells can be used as a model for function and biology of macrophages (Schwende et al. 1996).

4.1.1 Morphology studies of Vista-overexpressing celllines

First, we wanted to test if VISTA-GFP overexpressing cells were still able to differentiate properly into macrophages and if we could observe any differences. So, we differentiated the overexpressing celllines and the control cells for 3 days with 1 μ M PMA into macrophages and compared the morphology of a normal (Figure 4.3.1.1) and a culture with four times higher cell density (Figure 4.3.1.2). As you can see in Figure 4.3.1.1 the VISTA overexpressing cells still had the ability to differentiate into macrophages. They seemed to be more differentiated than the control cells and showed more pronounced macrophage phenotype with a stretched cell body and dendrites arising. The effect was already observable in THP-1 VISTA-GFP cells (b) but much stronger in HL-60 VISTA-GFP (d) cells. HL-60 empty vector cells did not show a typical macrophage morphology, while HL-60 VISTA-GFP cells looked highly differentiated with very long and thin dendrites.

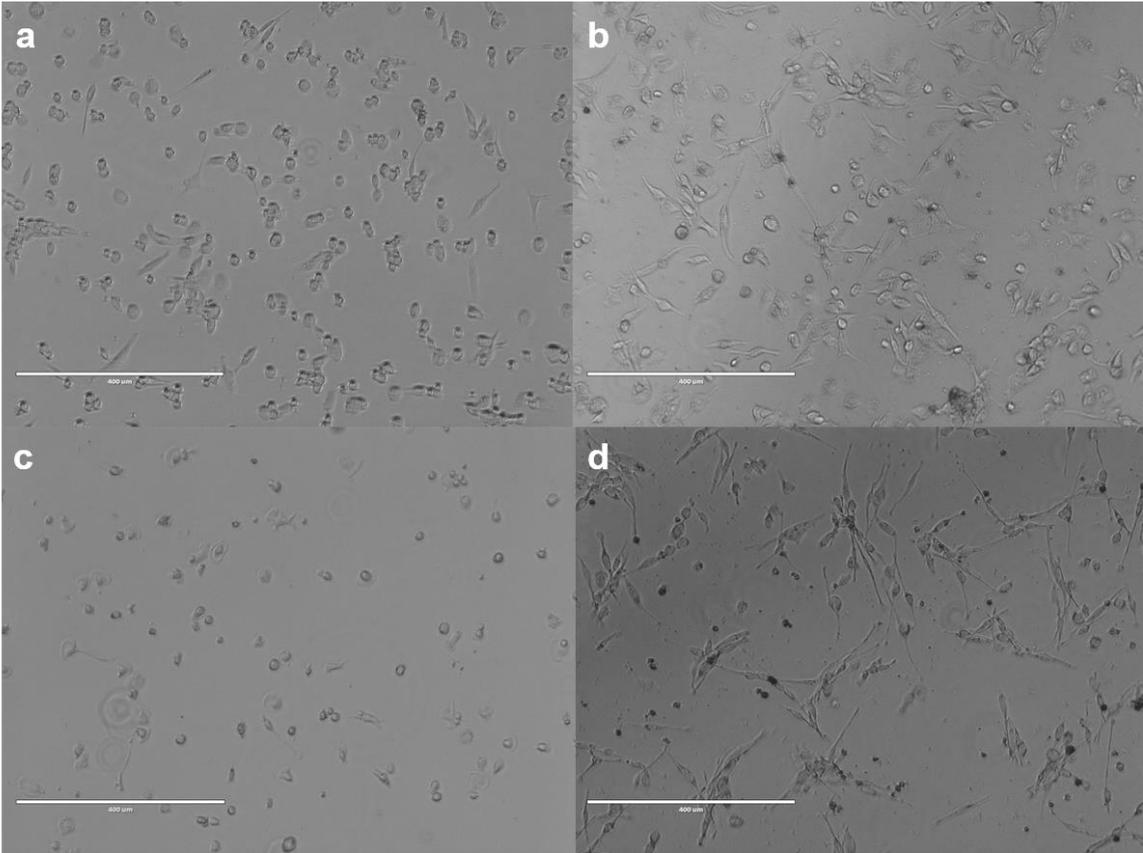

Figure 4.3.1.1: Morphology of THP-1 wt (a), THP-1 VISTA-GFP (b), HL-60 EV (c) and HL-60 VISTA-GFP celllines after 3 days with 1 μ M PMA

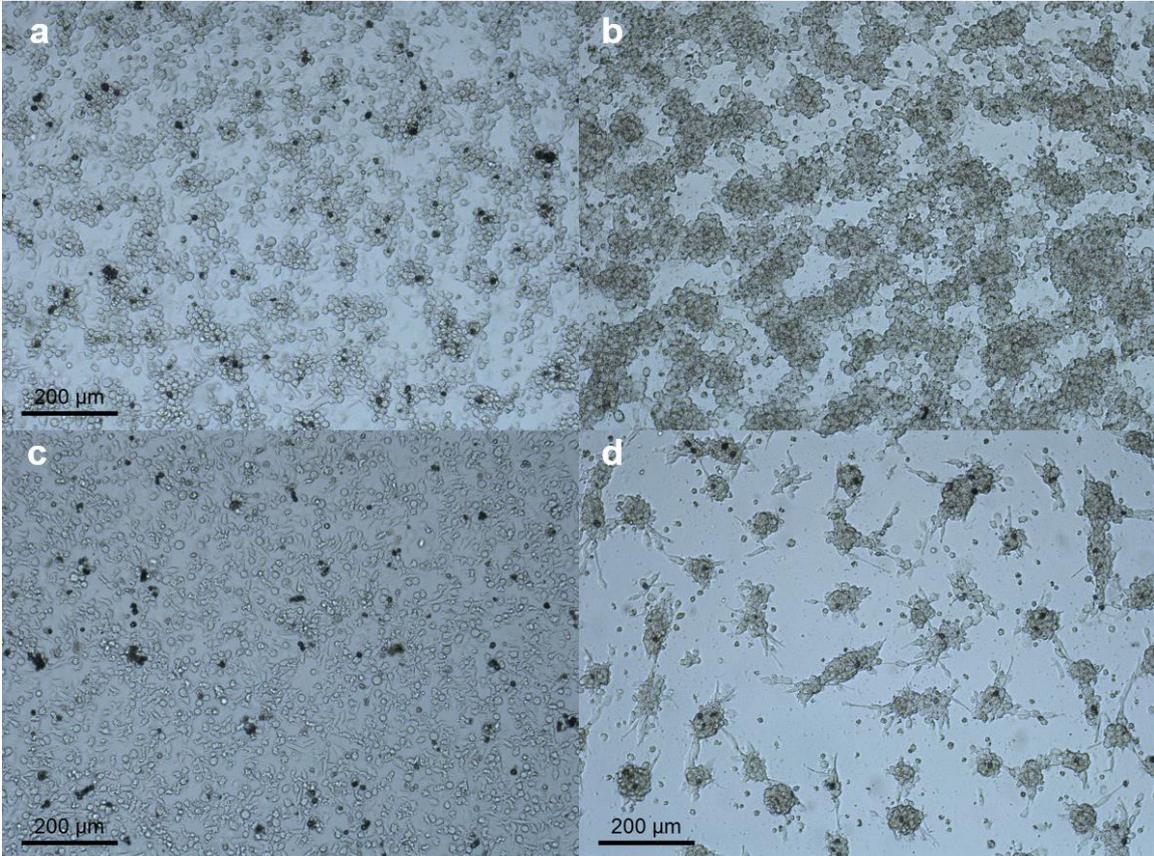

Figure 4.3.1.2: Morphology of THP-1 wt (a), THP-1 VISTA-GFP (b), HL-60 EV (c) and HL-60 VISTA-GFP celllines after 3 days of a culture with 1 μ M PMA in 4x times higher cell density

In Figure 4.3.1.2 one could see the effects of a high cell density on the different celllines. There it became obvious that VISTA-GFP cells were not only stronger differentiated than the control cells, but also showed much stronger adhesion. The VISTA-GFP cells tended to cluster together and had a strong cell-cell contact. This effect again was stronger for HL-60 cells but also observable for THP-1 cells. THP-1 wildtype cells were already more differentiated compared to HL-60 cells, because they were monocytic cells whereas HL-60 cells were undifferentiated promyeloblasts. In addition, the overexpression of VISTA was 1,5x stronger in HL-60 cells, than in THP-1 (Figure 4.1.2.5). So, it was reasonable that the effects are stronger in HL-60 cells.

4.1.2 Adhesion assays of Vista-overexpressing celllines

To test the effect of VISTA overexpression on the adhesion of the celllines we performed adhesion assays. Differentiated macrophages were always attached and adherent, but the undifferentiated celllines were suspension cells. So, we tested if the overexpression of VISTA led to an increased adherence of the undifferentiated suspension cells.

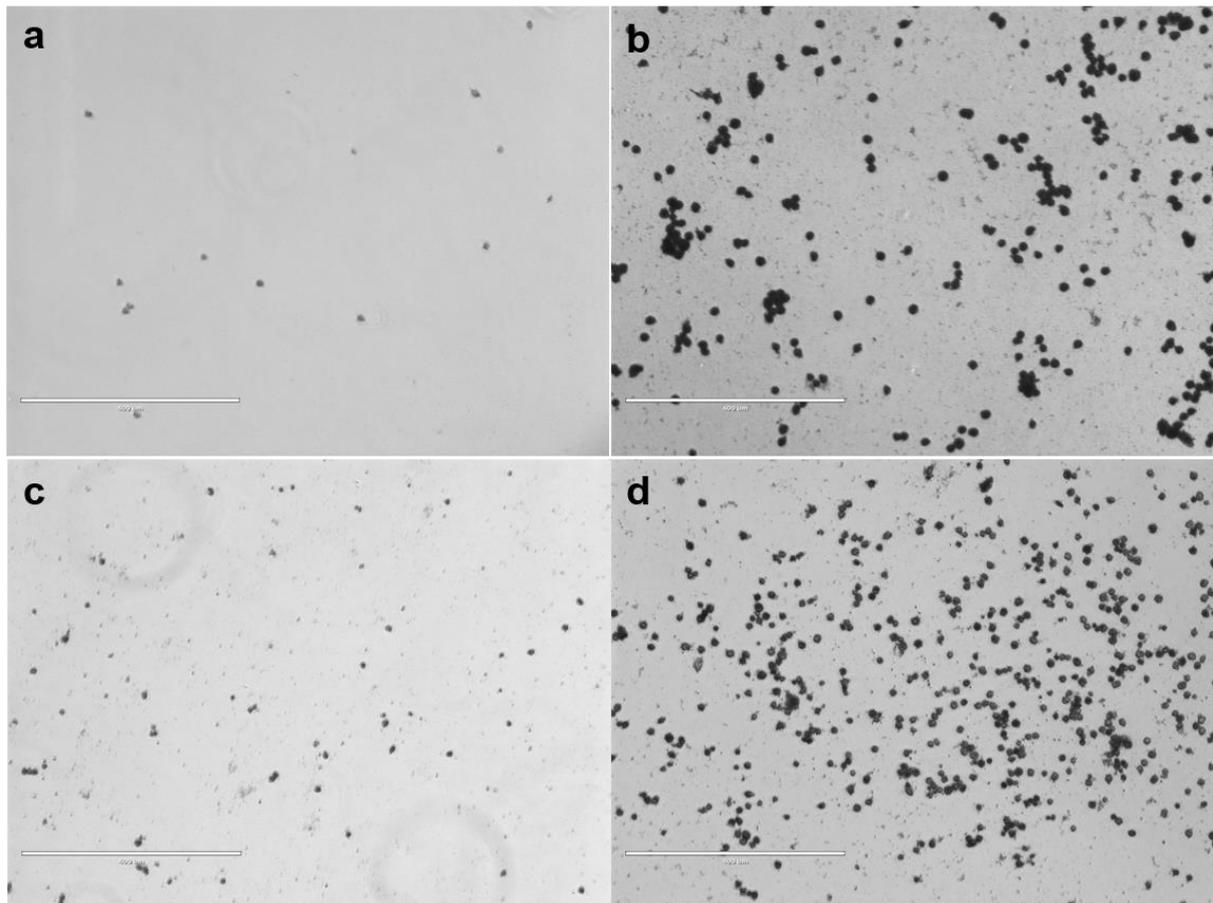

Figure 4.3.2.1: Adhesion of suspension cells a) THP-1 wt, b) THP-1 VISTA-GFP, c) HL-60 EV and d) HL-60 VISTA-GFP after 4 days

Indeed, overexpression of VISTA allowed suspension cells to become adherent and attached to the bottom of the wells (Figure 4.3.2.1).

Quantification of attached cells/well (Figure 4.3.2.2) showed for both celllines a higher adhesion for VISTA overexpressing cells after 4 days compared to the control cells.

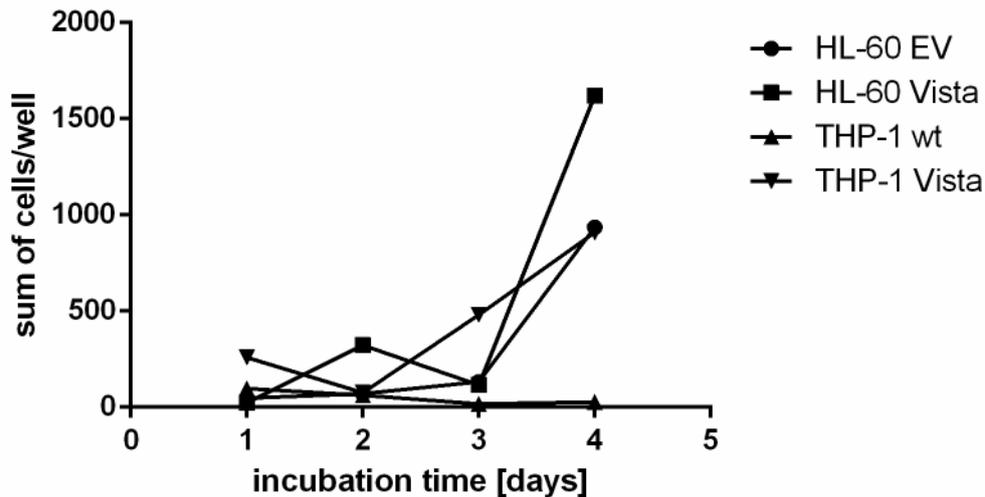

Figure 4.3.2.2: Example experiment: adhesion of suspension celllines, n=1 in quadruplets

The question arised how VISTA was increasing the adhesion and if soluble factors in the VISTA-GFP cell culture medium were sufficient to gain this increased adhesion. So, we replaced half of the culture medium with used medium of VISTA-GFP cells (+supernatant samples) and quantified the adhesion again after 3 days.

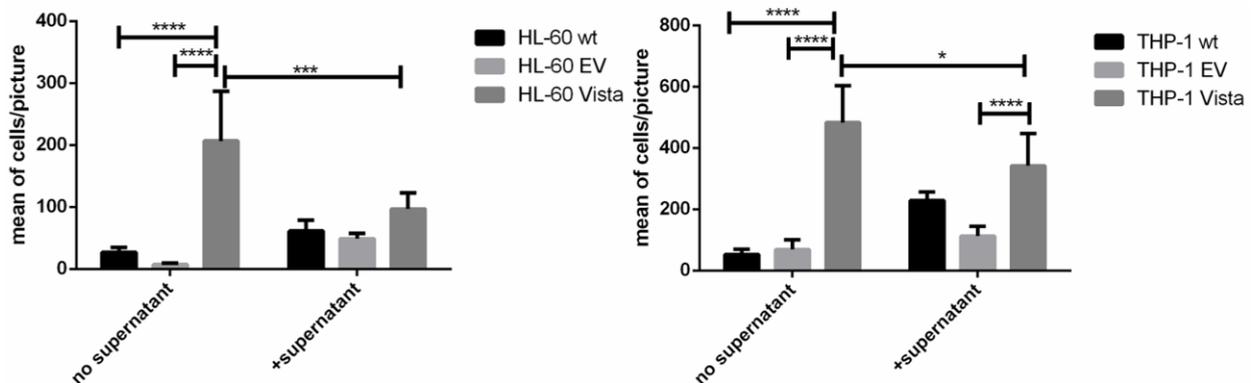

Figure 4.3.2.3: Example experiment: adhesion of suspension celllines with supernatant of VISTA-GFP cells, n=1 in triplicates

Without addition of supernatant there was a very high significant increase in adhesion for VISTA-GFP cells compared to wt or EV cells. This is true for HL-60 and THP-1 celllines. For HL-60 and THP-1 cells one could see a significant reduction of adhesion for VISTA-GFP cells after addition of supernatant. This was due to the used medium and the lack of nutrients (Figure 4.3.2.3). But you could still observe for both celllines an increase of adhesion for wildtype and empty vector cells. Displaying that despite the lack of nutrients, the medium of VISTA was sufficient for an increase in adhesion. But this increase was only very high significant for THP-1 EV cells compared to THP-1 VISTA-GFP cells after addition of supernatant. The reduced adhesion due to nutrient deficiency was too strong for VISTA-GFP cells to get significant results for the other celllines.

We also observed the reduction of adhesion due to lack of nutrients, when adding used empty vector medium instead of VISTA-GFP medium (Table 4.3.2.1). Causing a 0,47-fold adhesion compared to cells without supernatant addition. To reduce the stress of lacking nutrients and gain significant results, we also performed the adhesion assay

over one day. This led to a stable or only slightly reduced adhesion. Also, in only one day you could see a clear increase of adhesion due to VISTA-GFP medium on HL-60 wt and EV cells. This increase is significant for HL-60 EV cells (Table 4.3.2.1).

Table 4.3.2.1: x-fold difference in adhesion of suspension cells due to addition of supernatant

x-fold 3 days assay	+ EV supernatant	+ VISTA supernatant	x-fold 1 day assay	+ EV supernatant	+ VISTA supernatant
HL-60 wt		2,26	HL-60 wt	1,0	2,44
HL-60 EV		6,56	HL-60 EV		4,95 *
HL-60 VISTA	0,47		HL-60 VISTA	0,7	

So obviously the VISTA overexpressing cells secreted soluble factors in the medium which promoted the adhesion of cells.

4.1.3 Phagocytosis assays with VISTA overexpressing macrophages engulfing tumor cells

Macrophages are professional phagocytes which means that they are capable to engulf big pathogens, particles or apoptotic cells. To test the ability of phagocytosis is a standard test for functionality of macrophages. In this case the myeloid celllines HL-60 and THP-1 were differentiated into macrophages. The ability of phagocytosis was tested by phagocytosing the B-cell lymphoma celllines SudHL4 or SudHL10 because these are known celllines which were recognized and engulfed easily and with a high percentage. In addition, 1 $\mu\text{g}/\text{mL}$ of the antibody Rituximab against the B-lymphocyte surface molecule CD20 was added, to flag the B-lymphocytes for phagocytosis.

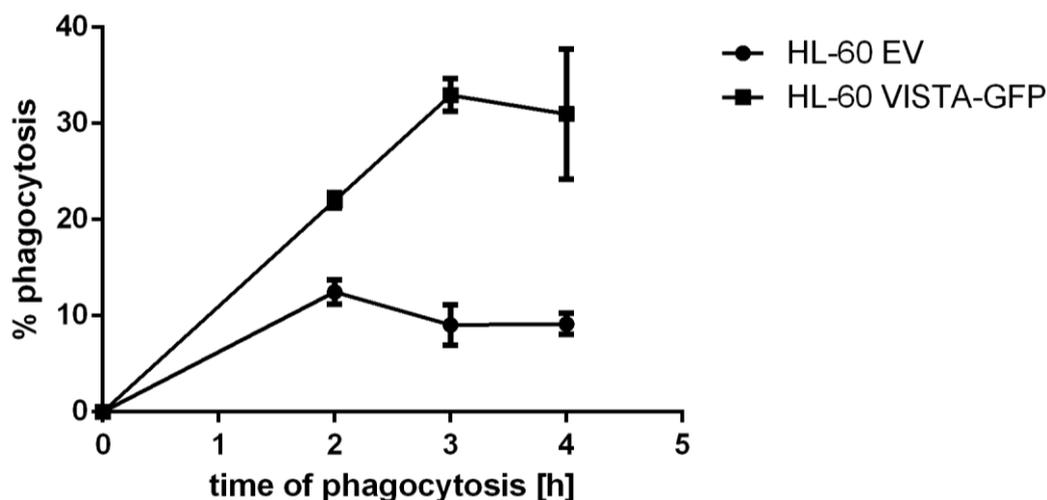

Figure: 4.3.3.1: Example experiment: phagocytosis of SudHL4 by HL-60 celllines (M0 macrophages), addition of 1 $\mu\text{g}/\text{mL}$ Rituximab, n=1 in triplicates

The phagocytosis of SudHL4 by HL-60 cells showed a big difference after 2 hours already (Figure 4.3.3.1). HL-60 VISTA cells showed a much higher percentage of cells which engulfed SudHL4 cells compared to HL-60 EV cells. The difference was even stronger after 3-4 hours of phagocytosis up to more than 25 % difference. HL-60 EV

cells did not have a high phagocytosis activity with a maximum of 12 %, which stayed constantly low. HL-60 VISTA-GFP cells however showed a much higher phagocytosis which increased up to 3 hours and remained high at around 31 %.

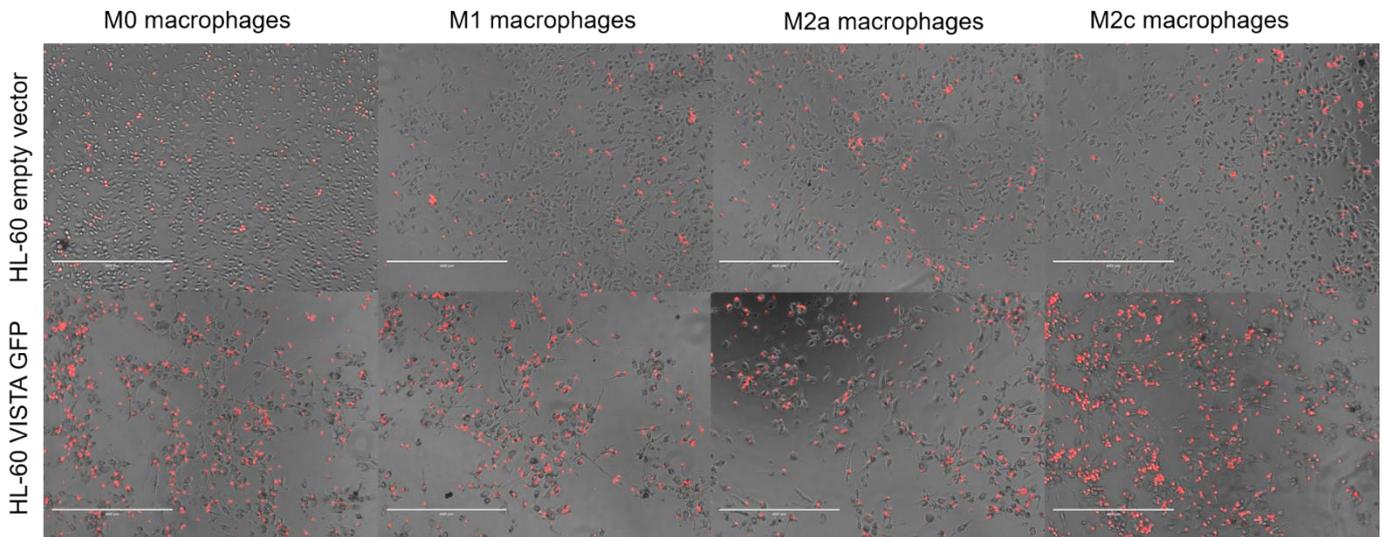

Figure 4.3.3.2: Pictures of phagocytosis of SudHL10 (red) by different macrophage types of HL-60 cells, addition of 1 $\mu\text{g}/\text{mL}$ Rituximab

But the celllines could not only be differentiated into M0 macrophages, but also into other macrophage types (Figure 4.3.3.2). For all macrophage types we could observe much more red tumor cells engulfed by the VISTA overexpressing macrophages, but also more tumor cells which were attached to the macrophages. This could be due to the enhanced adhesion and promoted cell-cell contact of VISTA overexpressing celllines. Phagocytosis first needs attachment of phagocyte and tumor cell to occur. So, the increased adhesion and cell-cell contact of VISTA overexpressing cells could also be a reason for the increased phagocytosis.

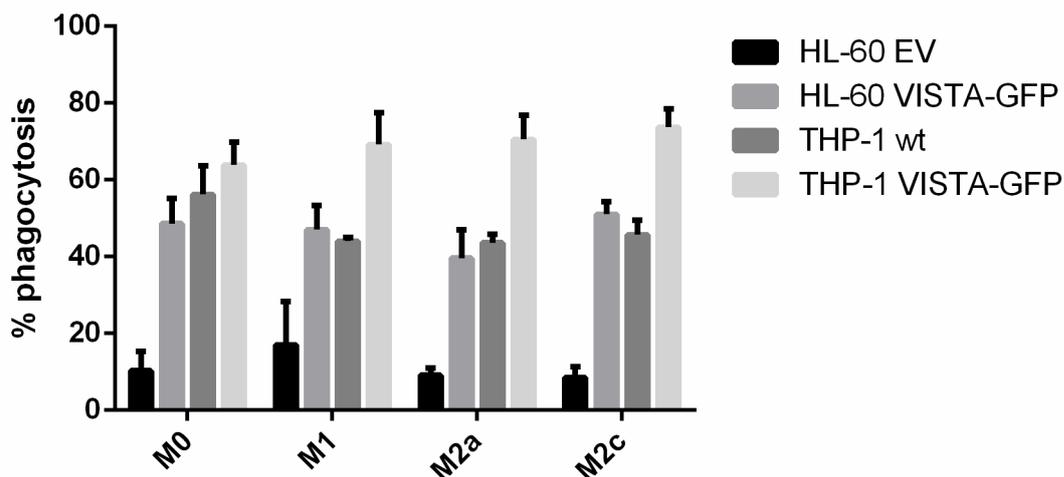

Figure 4.3.3.3: Example experiment: phagocytosis of SudHL10 for four hours by different macrophage types of HL-60 and THP-1 celllines, addition of 1 $\mu\text{g}/\text{mL}$ Rituximab, n=2 in duplicates

When we quantified the percentage of macrophages, which performed phagocytosis, HL-60 VISTA-GFP cells (between 39-51 %) showed much higher phagocytosis compared to the control cells HL-60 EV (between 8,5-17 %). The phagocytosis of THP-1 was already quite high for wildtype cells (43,5-56 %), limiting the possibility of

phagocytosis increase. But for all macrophage types, THP-1 VISTA-GFP cells also showed more phagocytosis (64-74 %) than the wildtype cells.

There was no clear difference observable for the different macrophage types. Normally you would expect the highest phagocytosis for M1 macrophages. M1 macrophages are typical killer macrophages with pro-inflammatory, bactericidal and phagocytic functions (Hesketh et al. 2017). M0 macrophages should have the second highest phagocytosis. M2 macrophages have a repair function in wound healing or tissue repair. Resident tissue macrophages are M2a type, while M2c macrophages turn off the damaging immune system (Galdiero et al. 2013). Because of their immunosuppressive function in the body, you would expect less phagocytosis of M2 macrophages. But former results with the wildtype celllines HL-60 and THP-1 of the Experimental Hematology at the UMCG showed the highest phagocytosis for M2c or M0 macrophage types. This is in accordance with my results.

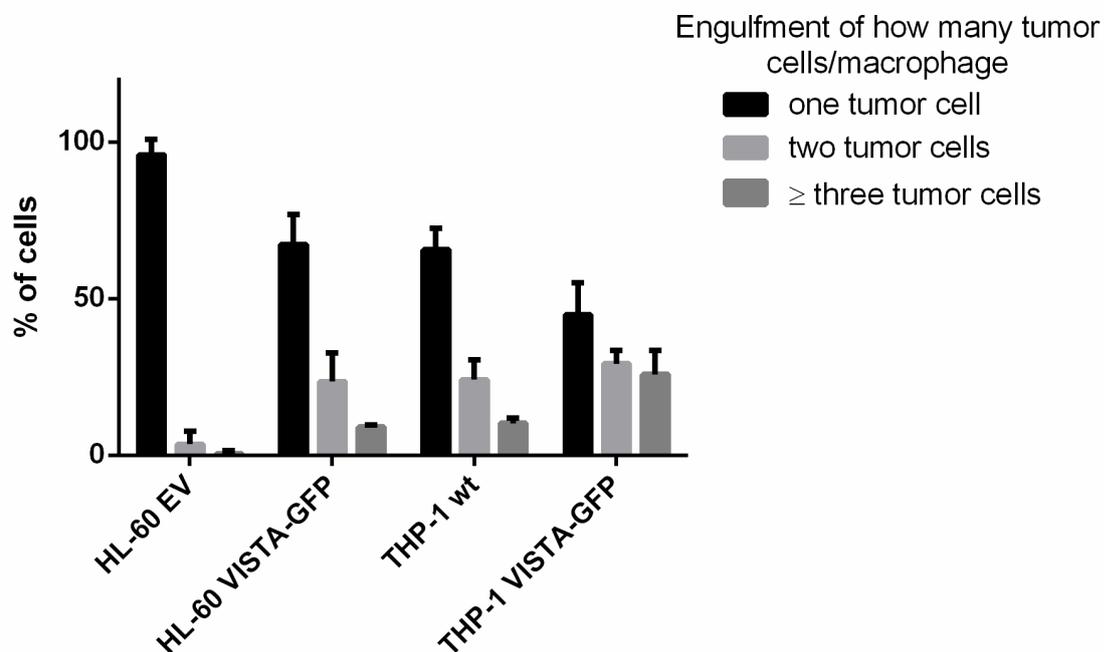

Figure 4.3.3.4: Example experiment: number of engulfed tumor cells after 4 h phagocytosis of SudHL10 by M2c macrophages of HL-60 and THP-1 celllines, addition of 1 $\mu\text{g}/\text{mL}$ Rituximab, n=2 in duplicates

VISTA-GFP overexpressing celllines did not only show more cells which did phagocytosis, but in addition they engulfed more tumor cells per phagocyte than the control cells (Figure 4.3.3.4). While 96 % of the phagocytosing HL-60 EV cells engulfed only one tumor cell, HL-60 VISTA-GFP cells were more active. Only 67,4 % engulfed one tumor cell, 23,5 % already two tumor cells and 9 % even three or more tumor cells. THP-1 wildtype cells engulfed comparable tumor cell numbers like HL-60 VISTA-GFP cells. But THP-1 VISTA-GFP cells also engulfed even more tumor cells/phagocyte than the wildtype. Only 45 % engulfed one tumor cell, 29 % two tumor cells and nearly 26 % engulfed three or more tumor cells. That showed that VISTA overexpression did not only lead to a higher percentage of macrophages performing phagocytosis, but also with a higher activity and more engulfed tumor cell per phagocyte.

Summarizing all three experiments of phagocytosis of SudHL10 cells by HL-60 and THP-1 macrophages (Figure 4.3.3.5) led to a high standard deviation. This was due to

the individual activation state of the cells. For example, one aspect for the variability was the cell number. A defined number of cells was seeded, but dependent on their condition, the number of cells which differentiated and how strong they differentiated and attached differed slightly. With that, the cell-cell contact, and activity of the macrophages also differed.

But one could still see a much higher phagocytosis for HL-60 VISTA-GFP cells than for HL-60 EV cells. For THP-1 cells, the difference was not so pronounced in the single experiments (Figure 4.3.3.3), leading to a weaker increased phagocytosis for THP-1 VISTA-GFP cells compared to THP-1 wt cells. But you can still observe the trend.

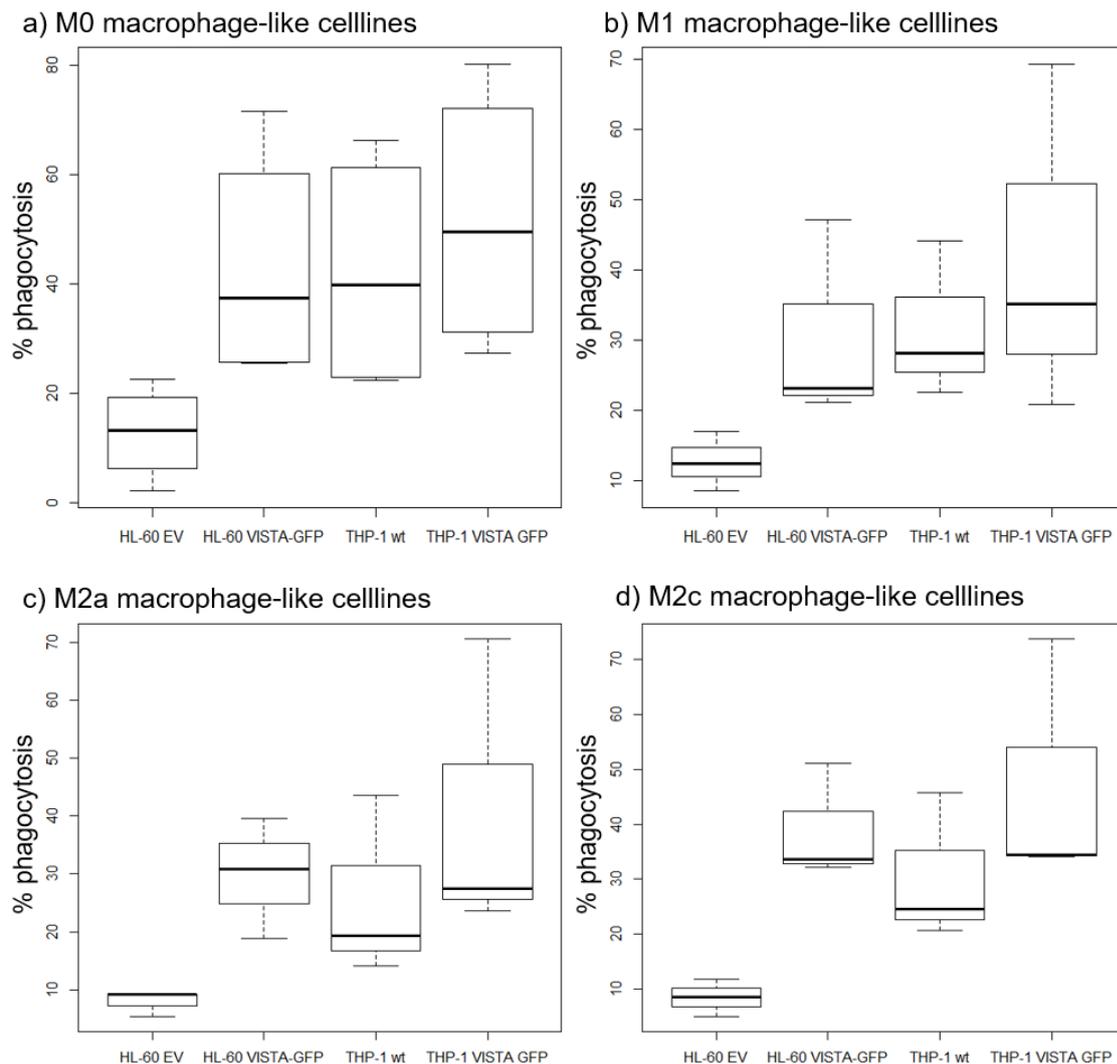

Figure 4.3.3.5: Summary of phagocytosis of SudHL10 by different macrophage types of HL-60 and THP-1 cell lines, macrophage type grouped, addition of 1 µg/mL Rituximab, n=4

Regarding the macrophage type difference for all three experiments of SudHL10 phagocytosis, there were still only small differences observable (Figure 4.3.3.6). But in accordance with the former results of the UMCG working group and the single experiment (Figure 4.3.3.3), M0 and M2c macrophages showed the highest percentage of phagocytosing macrophages.

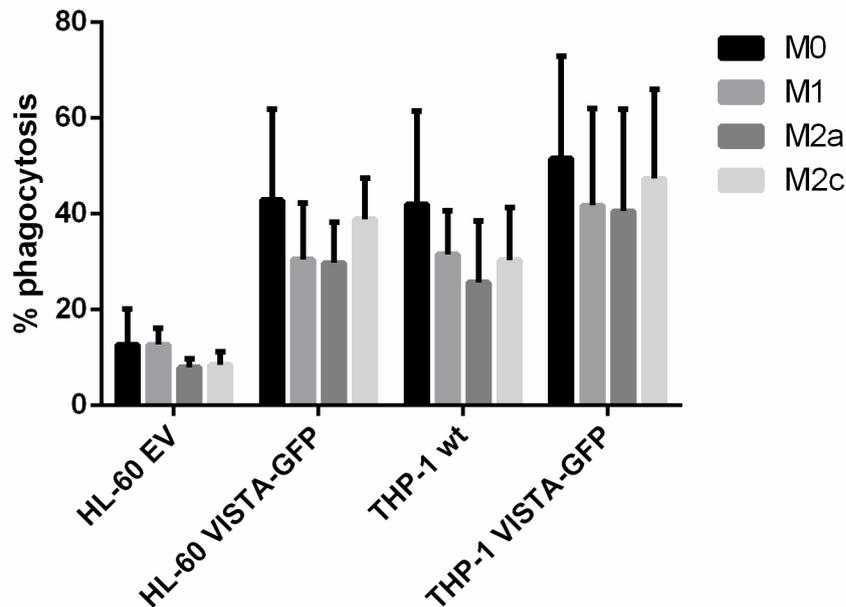

Figure 4.3.3.6: Summary of phagocytosis of SudHL10 by different of HL-60 and THP-1 celllines, cellline grouped, addition of 1 μ g/mL Rituximab, similar dataset like Figure 4.3.3.5, n=4

4.1.4 Phagocytosis assays of primary macrophages engulfing VISTA overexpressing tumor cells

So far, we only tested that macrophages with overexpression of VISTA showed a higher phagocytosis activity and function. We wanted to test now, if VISTA overexpression on the tumor cells also led to changes in phagocytosis. For that, we differentiated primary human monocyte derived macrophages into the different macrophage types and added the HL-60 and THP-1 celllines as tumor cells. We tested the phagocytosis with and without radiation of the tumor cells before phagocytosis. The radiation should induce apoptosis in the tumor cells leading to a higher phagocytosis rate of the cells.

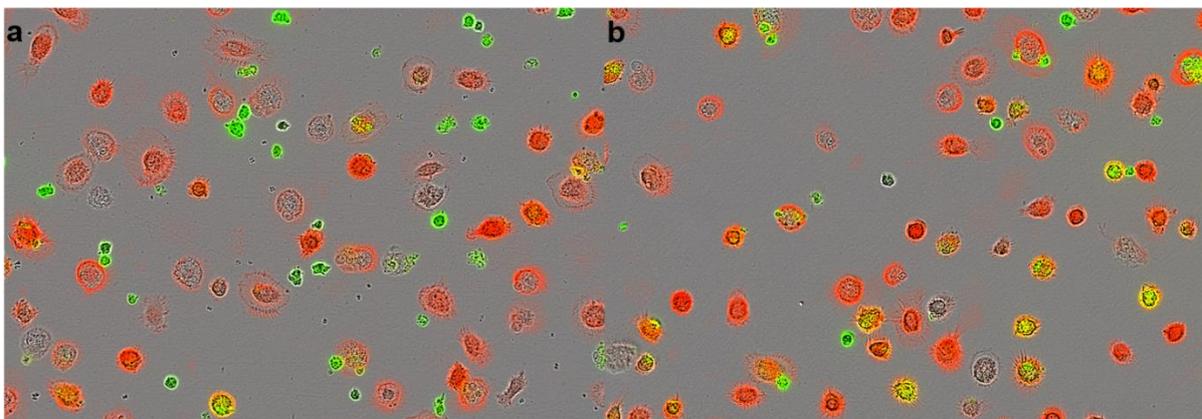

Figure 4.3.4.1: Primary M2c monocyte derived macrophages (red) phagocytosing HL-60 EV (green, a) and HL-60 VISTA (green, b)

The empty vector cells and the VISTA-GFP celllines expressed GFP and are green fluorescent. Macrophages were stained in red with CD11b. Macrophages which

engulfed a tumor cell appeared yellow (Figure 4.3.4.1). For HL-60 VISTA-GFP cells we could see more yellow macrophages and a higher rate of phagocytosis. For this assay it was not possible to count how many tumor cells are engulfed per macrophage due to technical reasons.

Non-radiated tumor celllines HL-60 and THP-1:

For non-radiated tumor celllines the difference of phagocytosis for control cells to VISTA-GFP overexpressing cells, was not strong for HL-60 cells. There was a small increase in phagocytosis for M1 (6 % increase to wt, 8 % increase to EV cells), M2a (15 % increase to wt, 9 % increase to EV cells) and M2c (4 % increase to wt, 9 % increase to EV cells) macrophages. For non-radiated THP-1 cells, the increase in phagocytosis was much stronger for VISTA overexpressing celllines. There was an increase on phagocytosis for THP-1 VISTA-GFP cells to THP-1 wt cells for M0 macrophages of 15 %, for M1 macrophages of 21 %, for M2a macrophages of 23 % and for M2c macrophages of 22 % (Figure 4.3.4.2).

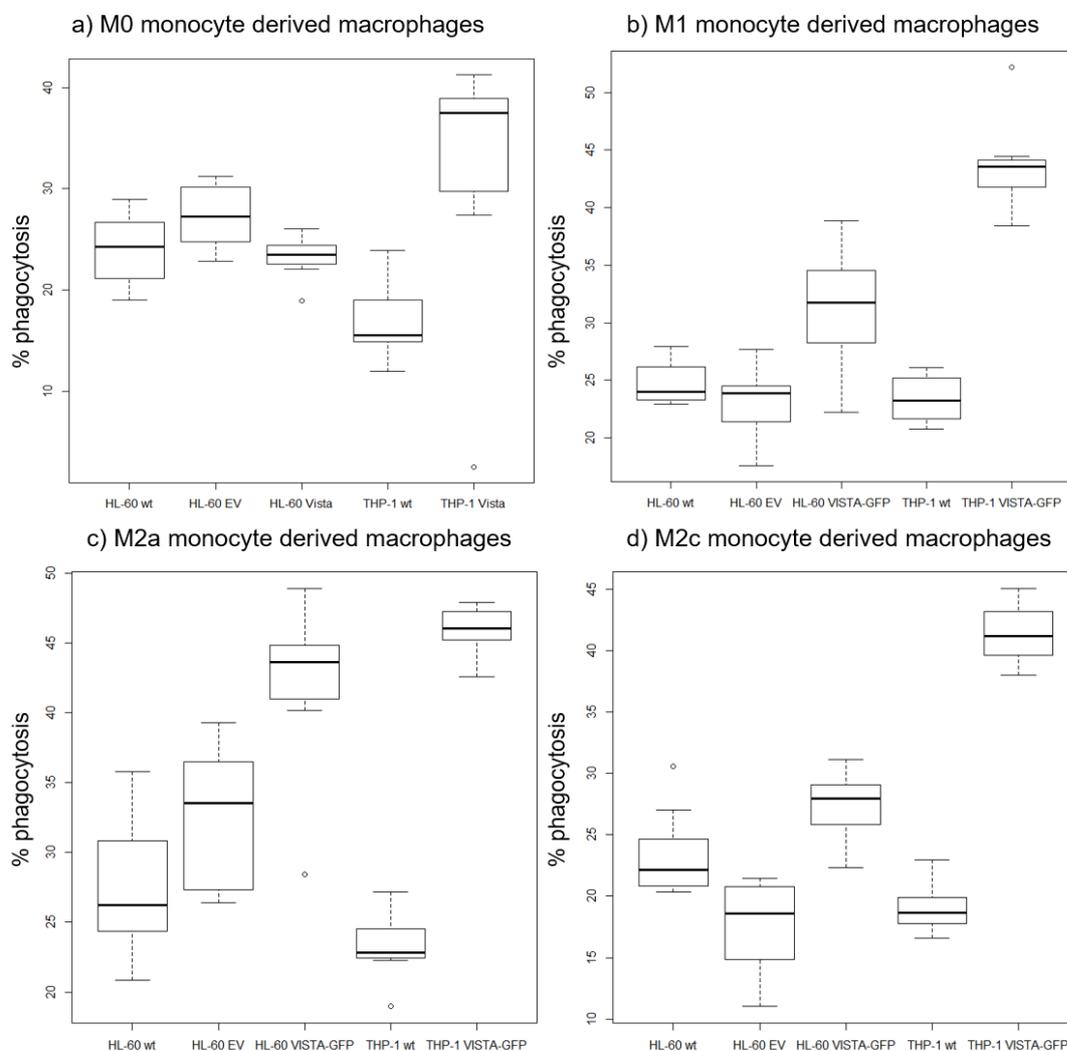

Figure 4.3.4.2: Example experiment: 300 min phagocytosis of non-radiated tumor celllines by monocyte derived macrophages, cellline grouped, n=2 in quadruplets

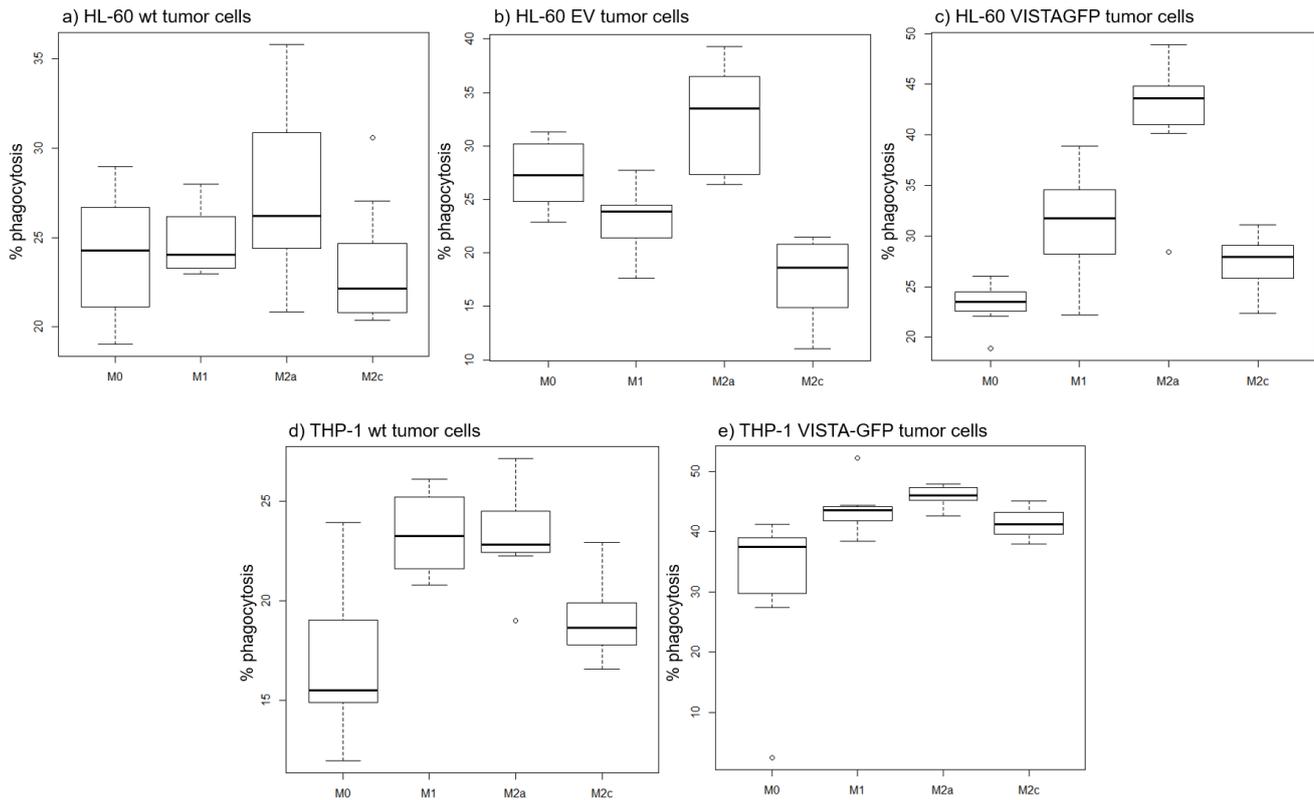

Figure 4.3.4.3: Example experiment: 300 min phagocytosis of non-radiated tumor celllines by monocyte derived macrophages, macrophage type grouped, similar dataset like Figure 4.3.4.2, n=2 in quadruplets

Regarding the macrophage type, M2a showed the highest percentage of phagocytosis for all HL-60 celllines. In contrast to the phagocytosis results of VISTA overexpressing macrophages, M2c macrophages showed much lower phagocytosis. M1 and M0 macrophages did not show the expected higher phagocytosis. For THP-1 cells M2a and M1 macrophages showed the highest phagocytosis, followed by M2c and M0 macrophages. We could assume that the percentage of phagocytosis was more dependent on the tumor cellline than on the macrophage type.

Radiated HL-60 tumor celllines:

For radiated tumor celllines, there was a stronger increase in phagocytosis for HL-60 VISTA-GFP cells compared to HL-60 EV cells (Figure 4.3.4.4) than for non-radiated cells (Figure 4.3.4.2). For M0 macrophages there was an increase of 20 %, for M1 macrophages an increase of 14 %, for M2a macrophages an increase of 20 % and for M2c macrophages an increase of 16 % phagocytosis for HL-60 VISTA-GFP compared to HL-60 EV cells. There were no big differences between the different macrophage types for HL-60 VISTA-GFP cells (Figure 4.3.4.5). For HL-60 EV cells, M1 and M2c macrophages showed the highest phagocytosis. But the difference to the VISTA-GFP cells was still higher than the difference between the different macrophage types.

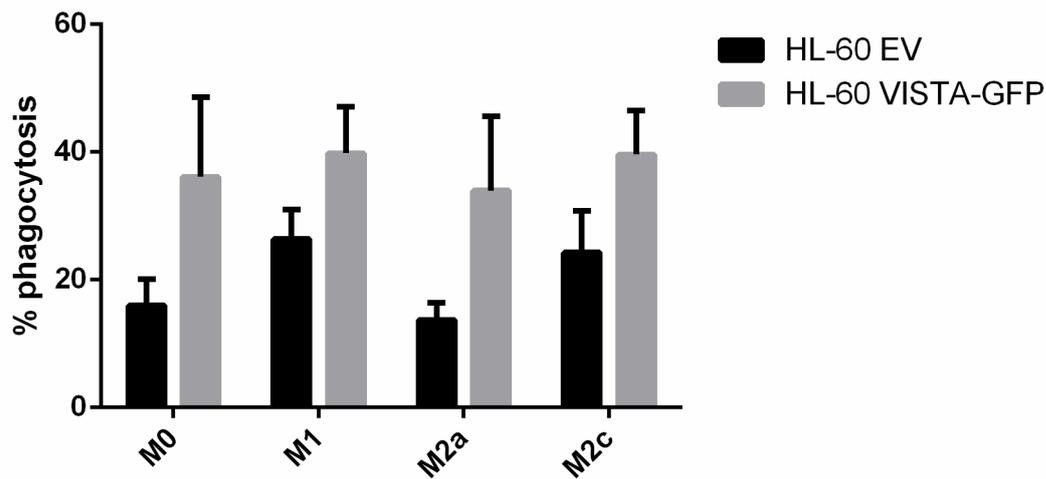

Figure 4.3.4.4: Example experiment: 120 min phagocytosis of radiated tumor celllines by monocyte derived macrophages, macrophage type grouped, n=3 in quadruplets

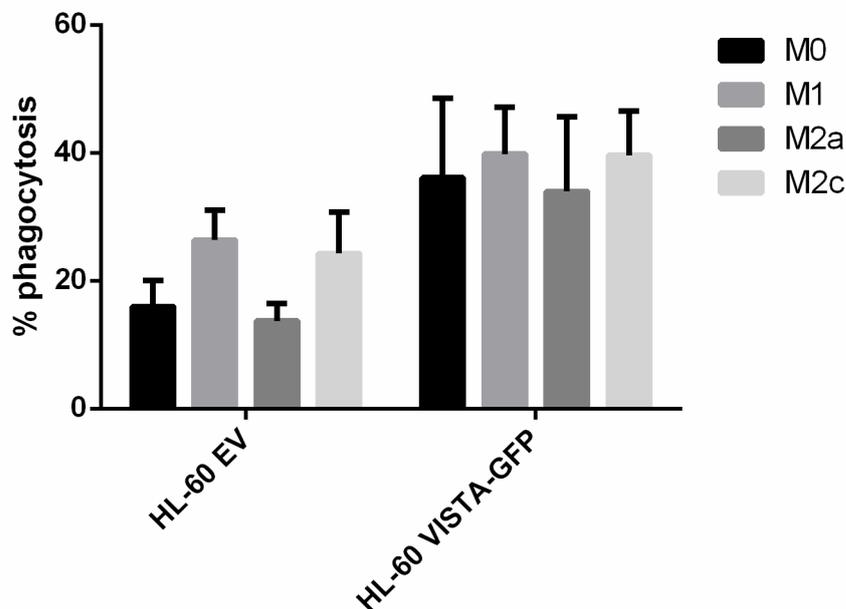

Figure 4.3.4.5: Example experiment: 120 min phagocytosis of radiated tumor celllines by monocyte derived macrophages, tumor cellline grouped, similar dataset like Figure 4.3.4.4 n=3 in quadruplets

We could conclude that the overexpression of VISTA led to an increased phagocytosis on both, the macrophage side and the tumor cell side.

4.1.5 Possible interaction partner

We wanted to investigate further the impact of VISTA overexpression on some other proteins and surface marker. For that, the HL-60 and THP-1 celllines were differentiated into M0 macrophages with PMA, before performing a qRT-PCR.

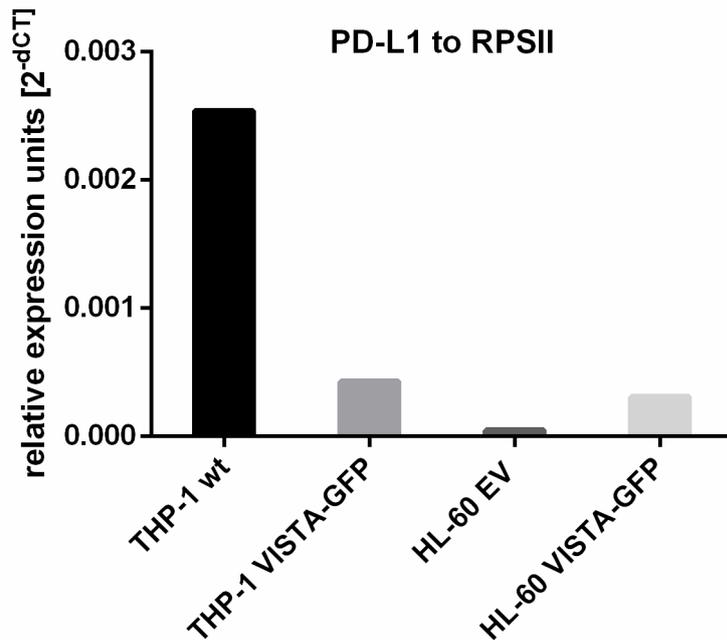

Figure 4.3.5.1: qRT-PCR of PD-L1 on M0 macrophage-like differentiated celllines w/o VISTA overexpression, RPSII as reference gene, n=1 in triplicates

First, we checked the effect on the PD-L1 expression (Figure 4.3.5.1). The PD-L1 expression was much higher on the celllines differentiated to M0 macrophages (Figure 4.3.5.1) compared to the myeloid suspension cells (Figure 4.1.2.2). We wanted to check if VISTA influences the PD-L1 expression because of possible resistance mechanisms. VISTA and PD-1 have a similar but non-redundant function and VISTA shows a high homology to PD-L1. One possible reaction of the cells could be a downregulation of PD-L1 when VISTA is overexpressed. But we only saw a clear downregulation for THP-1 VISTA-GFP cells compared to the wildtype. For HL-60 cells, the HL-60 VISTA-GFP cells showed a higher PD-L1 expression than the HL-60 EV cells. So, the downregulation of PD-L1 was no mandatory consequence of VISTA overexpression, but for some celllines like THP-1 there might be an effect of VISTA overexpression.

In addition, we tested A Disintegrin and metalloproteinase domain-containing protein 10 (ADAM10) and Mothers against decapentaplegic homolog 3 (Smad3) as possible interaction partners of VISTA (Figure 4.3.5.2).

ADAM10 is a sheddase and sheds many surface proteins. In addition, ADAM10 is responsible for dendritic spine formation and maturation and is inhibited in breast cancer treatment (Liu et al. 2006). Because of the effects of the MMP and ADAM inhibitor TAPI-2 in chapter 4.2.2, we tested the effect of VISTA overexpression on the ADAM10 RNA level. Smad3 was proposed as a possible interaction partner of VISTA by the STRING network and Yeast-two-hybrid system (Szklarczyk et al. 2019), so we tested the RNA levels of Smad3 as well. Smad3 is a transcriptional modulator and signal transducer which is activated by transforming growth factor- β (TGF- β) and activin type 1 receptor kinases (Seong et al. 2007).

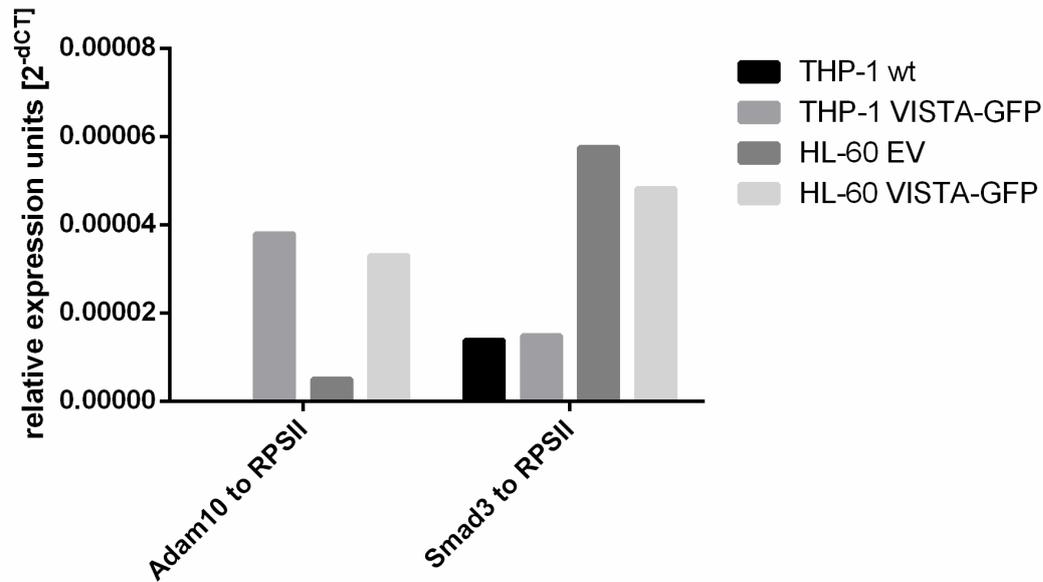

Figure 4.3.5.2: qRT-PCR of Adam10 and Smad3 on M0 macrophage-like differentiated celllines w/o VISTA overexpression, RPSII as reference gene, n=1 in triplicates

For ADAM10 we could see an increase in RNA levels for both VISTA overexpressing celllines. VISTA overexpression seemed to promote the transcription of ADAM10 but the amounts of ADAM10 RNA were still quite low. For Smad3 there was a bigger difference for the different celllines observable than for VISTA overexpression. HL-60 cells expressed three times more Smad3 than THP-1 cells. Between control cells and VISTA-GFP cells there was no difference. So, the overexpression of VISTA surprisingly did not influence RNA levels of its proposed interaction partner Smad3.

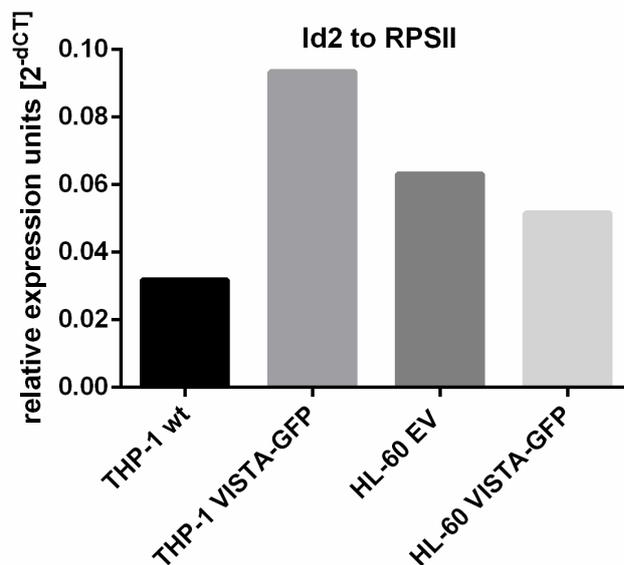

Figure 4.3.5.3: qRT-PCR of Id2 on M0 macrophage-like differentiated celllines w/o VISTA overexpression, RPSII as reference gene, n=1 in triplicates

Inhibitor of DNA binding 2 (Id2) is a transcriptional regulator that plays a role in negative regulation of cell differentiation. It followed the VISTA expression in EMT model and enhanced migration and invasiveness (Coma et al. 2010; Li et al. 2012). In addition, Id2 was highly expressed in monoblastic leukemia cells like THP-1, but weakly

expressed in myeloblastic leukemia cells like HL-60. Id2 level increased with macrophage differentiation via PMA (Ishiguro et al. 1996). So, we wanted to test if Id2 level also followed the VISTA overexpression in our celllines (Figure 4.3.5.3).

Indeed, the Id2 RNA level were not lower anymore in HL-60 cells compared to THP-1 cells after PMA differentiation. For THP-1 cells the expression level increased nicely with VISTA overexpression, but for HL-60 cells not. We could assume that Id2 levels did not mandatory follow VISTA expression levels in celllines, but for some celllines like THP-1 there might be an effect of VISTA overexpression.

Beside the RNA measurements, we also investigated the occurrence of some typical macrophage surface marker via flow cytometry. Again, we differentiated the celllines with VISTA-GFP overexpression and control cells with PMA to M0 macrophage-like cells. But for flow cytometry analysis we needed to trypsinase them before staining and surface expression analysis. This can influence some surface marker. The flow cytometry technique has the advantage that we can gate exclusively on properly EV or VISTA transfected cells via the fluorescence of GFP (gating strategy attached in appendix Figure 7.2.10).

We checked for the following surface marker:

Table 4.3.5.1: Table of surface marker used for flow cytometry analysis of M0 macrophage-like celllines w/o VISTA overexpression (adaptation of (Röszer 2015) and (Duluc et al. 2007))

Surface marker	Function	Expression on which macrophage type?
Cluster of differentiation 14 (CD14)	crucial for M1 polarization, cellular migration and phagocytic properties	M1 macrophages
CD80	Binds to CD28 and CTLA-4 or PD-L1. Triggers second costimulatory signal to T-cells via CD28	Activated M1 macrophages
CD86	Binds to CD28 and CTLA-4 or PD-L1. Triggers second costimulatory signal to T-cells via CD28	Activated M1 macrophages
CD163	High affinity scavenger receptor and functions as innate immune sensor for gram-positive and gram-negative bacteria	M2a and M2c macrophages
Major histocompatibility complex-I (MHC-I)	Presents intracellular antigens towards CD8 ⁺ T-cells	All cells with a nucleus
MHC-II	Presents extracellular antigens towards CD8 ⁺ T-cells	M1 and M2a macrophages

The flow cytometry measurements of CD14 showed a different result for HL-60 and THP-1 cells (Figure 4.3.5.4). While THP-1 wt cells did not express the M1 marker CD14, HL-60 EV cells expressed CD14. This was surprising because THP-1 wt cells already showed a quite high phagocytosis while HL-60 EV cells showed a very low phagocytosis activity as M0 macrophages. High phagocytosis could be a hint for a M1 like differentiation which would go ahead with CD14 expression. THP-1 VISTA-GFP cells, HL-60 VISTA-GFP cells and HL-60 EV cells showed CD14 expression as M0 macrophages.

VISTA overexpression led to measurable CD14 expression for THP-1 cells displaying a hint for increased differentiation via VISTA. For HL-60 cells, which already showed CD14 expression, there was no further increase in expression due to VISTA overexpression.

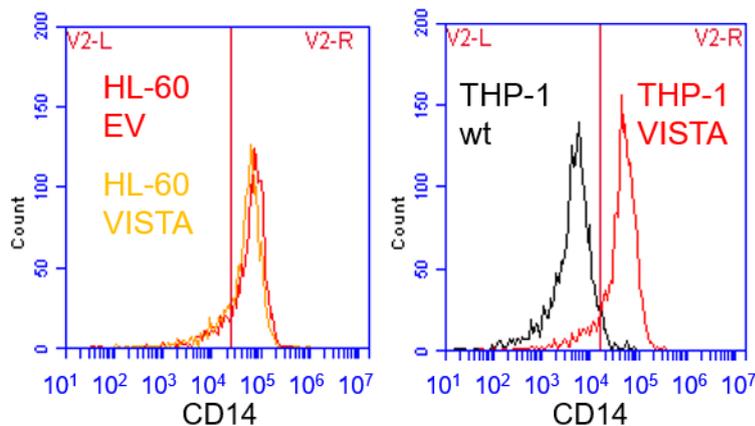

Figure 4.3.5.4: Flow cytometry analysis of CD14 surface expression on differentiated M0 macrophage-like celllines w/o VISTA overexpression

The results for CD80 and CD86 were not consistent (Figure 4.3.5.5). CD80 and CD86 have the same function and should react in the same manner. While we could observe a small increase in CD86 expression for THP-1 VISTA-GFP and HL-60 VISTA-GFP cells, this was not observable for CD80. This could be due to the very weak CD80 staining for all celllines. The increase in CD86 expression due to VISTA overexpression is stronger for HL-60 cells than for THP-1 cells and could be a hint for stronger differentiation and activation due to VISTA.

Also, the results for CD163 were not consistent between the celllines (Figure 4.3.5.6). THP-1 VISTA-GFP showed a small increase in the M2 marker compared to the wildtype. The HL-60 celllines showed no difference. With that the THP-1 VISTA-GFP cells showed more M1 and M2 marker but only a small increase in activation marker. HL-60 VISTA-GFP cells showed a higher expression of the activation marker CD86 but no other strong differences compared to the empty vector cells. So, the measurement of surface marker did not show a changed phenotype or strong macrophage type differences for the celllines with VISTA-GFP overexpression. But the VISTA-GFP celllines were slightly more differentiated and activated compared to the wt or EV cells.

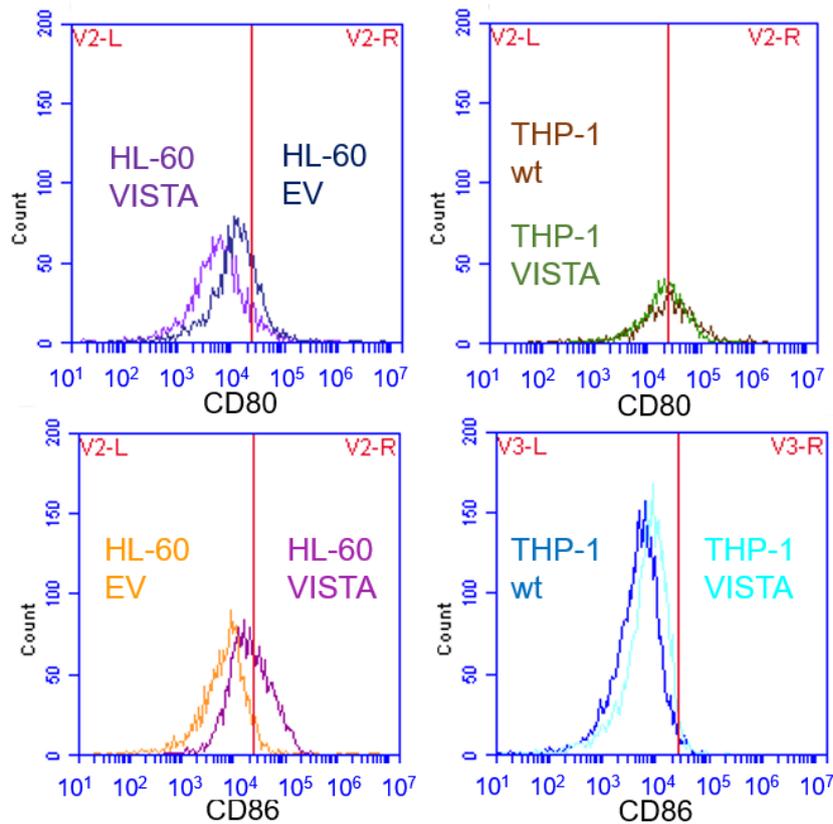

Figure 4.3.5.5: Flow cytometry analysis of CD80 and CD86 surface expression on differentiated M0 macrophage-like cell lines w/o VISTA overexpression

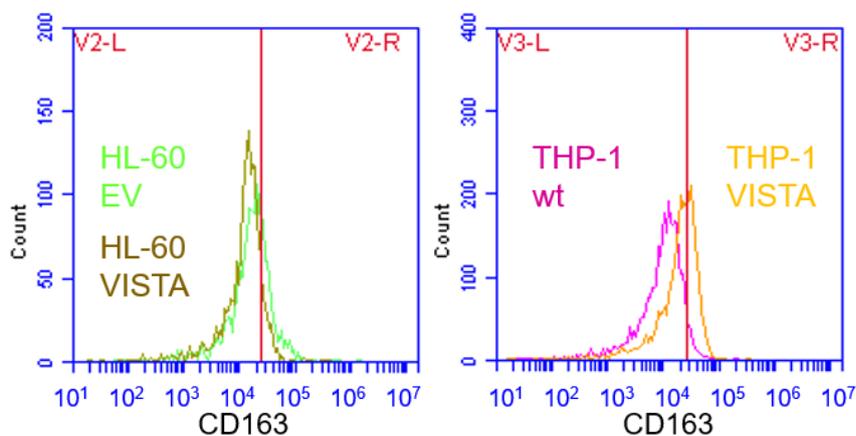

Figure 4.3.5.6: Flow cytometry analysis of CD163 surface expression on differentiated M0 macrophage-like cell lines w/o VISTA overexpression

Beside the classical macrophage type marker, we also checked for MHC clusters. The immunogenic function of macrophages is the presentation of Antigens towards CD8⁺ T-cells via MHC complexes. In Figure 4.3.5.7 one could observe a reduced surface expression of MHC-I and MHC-II cluster for VISTA-GFP overexpressing cell lines. The MHC-II complex was also verified as an interaction partner of VISTA via GFP-pull out by the Experimental Hematology of the UMCG (data not shown).

As a negative checkpoint regulator, VISTA leads to less T-cell activation. VISTA overexpression seems to cause less antigen presentation and less activation of T-cells. This is interesting in combination with the increased phagocytosis of VISTA

overexpressing macrophages (chapter 4.3.3 and 4.3.4). VISTA overexpression led to more phagocytosis which would assume more immune stimulation, but due to less complexes for antigen presentation, the increased phagocytosis could still lead to less T-cell activation.

This is a complete unknown interaction so far and reveals a much more complex immunoinhibitory role of VISTA on Antigen Presenting Cells, which should be further investigated.

5 Discussion

5.1 VISTA distribution in cell fractions and cell types

5.1.1 VISTA protein purification and characterization

There was no purification protocol of the IgV-VISTA domain established when we started this project. Both tested protocols led to soluble and pure IgV-VISTA protein and can be assumed as useful and successful.

The separation of proteins by SEC is mostly dependent on the protein size, but also on the conformation of the protein and of its interactions with the stationary phase (Striegel et al. 2009). All chromatograms showed peaks with comparable volumina of elution. The column could separate proteins of 3-70 kDa. The calculated molecular mass of the first peak was far over this, displaying that it was caused by protein aggregates. But the SDS gel showed a single band at 20 kDa for the fraction, exhibiting that the aggregates were made of IgV-VISTA protein. The biggest peak showed a calculated molecular mass between 35-40 kDa. Accordingly, the main amount of VISTA was appearing as a dimer and only a very small percentage of IgV-VISTA was appearing as a monomer. Therefore, the monomer-dimer equilibrium is strongly shifted towards the dimer.

In general, the renaturation of dialysis resulted in higher amounts of correctly folded and not aggregated protein. After dialysis 78,7 % of the protein were not aggregated, while renaturation on the column only led to 52,6 % of renatured protein. Both methods provided comparable protein amounts, so the dialysis should be used preferential.

The higher amounts of correctly folded protein after dialysis are reasonable because the folding is assisted due to the dialysis buffer. The dialysis buffer contains oxidized and reduced Glutathione (GSSG/GSH), which is able to bind and refold cysteine-cysteine connections of proteins. The IgV-domain contains four additional cysteines (five cysteines in total) that are not present in other related proteins of the Ig superfamily (Xu et al. 2018), so we can conclude that the IgV domain of VISTA is probably able to build many cysteine-cysteine connections in the oxidized extracellular environment. The assisted folding by GSSG/GSH allows a rebinding of the different cysteines, until all cysteines are bound to the correct binding partner. This leads to a higher proportion of correctly folded protein than the non-assisted refolding on the Ni²⁺-column. It is not clear whether the IgV-VISTA domain was functional after this purification and renaturation, but a soluble protein suggests a correctly folded protein, which is probably functional.

It was published that VISTA can build dimers (Sakr et al. 2010). Our analysis confirmed the former hypothesis that VISTA preferentially appears dimerized in solution, which is supported by the fact that VISTA IgV contains several cysteines that could build cysteine-cysteine connections between two IgV domains. With its tendency of dimerization, VISTA could bind VISTA proteins on another cell surface, activating the T-cell VISTA receptor and its immunoinhibitory pathways (Figure 1.3.3.3) (Liu et al. 2015; Yoon et al. 2015).

5.1.2 VISTA expression in different cell types

For both, celllines and primary cells, our results confirmed that the VISTA expression is higher on Antigen Presenting Cells (APCs) than on T-cells (Deng et al. 2016). This demonstrates that VISTA is not a typical NCR like PD-1 but more related to its ligand PD-L1. For VISTA signaling, the extrinsic T-cell function seem to be more important as it shows higher expression, than the intrinsic T-cell function.

Like expected, the VISTA expression was higher on primary cells than on celllines. The expression of VISTA on tumor cells was discovered recently (Wu et al. 2017; Wang et al. 2018; Mulati et al. 2019; Böger et al. 2017; Mulati et al. 2019; Edwards et al. 2019; Shrestha et al. 2018; Blando et al. 2019; Loeser et al. 2019; Muller et al. 2019; Hong et al. 2019).

In screenings before, tumor cells were assumed as VISTA negative because of the low VISTA expression compared to immune cells. Celllines are produced by tumor cells so we expected no or only very low VISTA amounts on tumor cell-derived celllines. As confirmed nowadays, the VISTA expression is only on some tumor cells and in low amounts, so our preliminary results fitted to these studies. In addition, I could see differences between the celllines.

The more differentiated monocytic celllines like THP-1 showed higher expression of VISTA than undifferentiated or promyeloid blast celllines like HL-60. This is reasonable because VISTA was originally discovered as the differentiation protein *Dies1*. It is important for the stem cell differentiation in embryonic development and differentiates cells dependent and independent of the bone morphogenetic protein-4 (BMP-4) pathway (Oliveira et al. 2016). So higher amounts of VISTA could lead to increased differentiation. This could be one aspect why celllines with higher VISTA expression are more differentiated. For the future there should be more insight if there is a link of differentiation and VISTA expression in tumor cells or a more important link of immunological state of the tumor and VISTA expression.

5.1.3 VISTA expression in cellular fractions

VISTA in vesicles

The storage of VISTA in endocytic and secretory vesicles showed a high similarity to the model NCR CTLA-4 (Linsley et al. 1996). The surface expression of CTLA-4 varies depending on the T-cell activation and shows a high dynamic of endocytosis and exocytosis. It is also known that VISTA is endocytosed rapidly but with a constant high cell surface expression on myeloid cells (Deng et al. 2016).

Although there were indications of VISTA expression in the cytoplasm (Deng et al. 2016; Liu et al. 2018), VISTA expression was only investigated on the cell surface via flow cytometry so far. My results strongly indicated that there are much higher VISTA amounts expressed and stored in vesicles than expressed on the cell surface.

The storage of VISTA in vesicles could enable a fast reaction to immunogenic stimuli and a fast regulation of the VISTA surface expression. VISTA vesicles could adapt the cell surface expression rapidly via endocytosis and exocytosis with the plasma membrane.

VISTA in nuclei

The expression of VISTA in the nucleus was unexpected and needs further investigation. VISTA is a membrane protein and does not contain a classical nucleus import motif. Nevertheless, the expression of VISTA in the nucleus was observable with four different VISTA antibodies and in the VISTA-GFP transfected cells, which allowed me to exclude any unspecific antibody reaction.

But the nucleus expression of VISTA confirms the high similarity of VISTA with PD-L1 which is expressed in the nucleus as well. VISTA is also called PD-L1-like ligand because of the high homology of VISTA and PD-L1 and shows a similar structure (Lines et al. 2014a; Wang et al. 2014; Lines et al. 2014b; Baksh und Weber 2015). PD-L1 does not contain any classical nucleus import motif as well, but shows interaction with nuclear import/export proteins in its interactome (Escors et al. 2018).

In addition to its function of T-cell inhibition, an anti-apoptotic role with molecules in the nucleolus is discussed for nuclear PD-L1. Nuclear PD-L1 is not only upregulated due to chemotherapy with Doxorubicin, but also in strongly apoptosis resistant circulating tumor cells (Ghebeh et al. 2010; Satelli et al. 2016). The nucleus expression seems to enhance the apoptotic resistance and is correlated with a bad prognosis if found in tumor cells.

VISTA also shows an anti-apoptotic role and is induced as a downstream target of p53 in response to stress and DNA damage (Yoon et al. 2015). With the high homology to PD-L1 a similar function could be proposed for VISTA. To optimize the immunotherapy of tumor, the nucleus expression of VISTA in (circulating) tumor cells should be considered and investigated for the future.

VISTA in exosomes

While there are indications of the extracellular VISTA domain to be shedded and released in the medium to operate as a signal molecule (Sakr et al. 2010), there were no indications yet of VISTA being present in exosomes. This finding showed a complete new possible pathway of cell-cell-communication via VISTA in secreted exosomes and should be investigated further.

VISTA can bind itself and could forward the VISTA signal in a soluble or membrane-bound form like exosomes. This signaling pathway would not require direct binding of immune cells via VISTA for immunosuppressive signaling (Yang et al. 2017; Mehta et al. 2019; Prodeus et al. 2017). It was shown that the soluble IgV domain of VISTA binds the VISTA receptor on T-cells and is sufficient to temper the immune reaction of T-cells (Prodeus et al. 2017). So, VISTA containing exosomes could be an important way of immune evasion of tumor cells in the tumor microenvironment.

My results about the intracellular trafficking of VISTA are summed up in Figure 5.2.1.

5.2 Effect of stimulation

Effect on VISTA vesicles

Based on 5.1.3, I tested if VISTA vesicles are released due to immunogenic stimulus via particle analysis. The results showed a decrease of VISTA vesicles in the cytosol due to immunogenic stimulus. The particle analysis gave no information about increase of VISTA surface expression, but the standard transport mechanism of proteins in endosomes is exocytosis to the plasma membrane.

The fact that VISTA vesicles seemed to be released to the cell surface due to immunogenic stimulation is reasonable. As a negative checkpoint regulator, the main function of VISTA, is the downregulation of immune reactions. To tender the reaction of the immune system in inflammatory conditions, you need more inhibitory molecules on the cell surface than in resting conditions. As already assumed in 5.1.3, the vesicular storage of VISTA enables a fast response and upregulation of surface VISTA towards immunogenic stimuli. This is a strong coherence to CTLA-4 which is also transported to the cellular membrane due to immunogenic stimulation (Linsley et al. 1996).

So far, the expression level of VISTA was only measured by flow cytometry on the cell surface or by RNA level. The fact that most of the VISTA protein is stored in vesicles which can be released to the surface within a few minutes showed a new dimension of dynamic in VISTA surface expression. The tumor microenvironment is an inflammatory environment with many immunogenic stimuli which could have an impact on the surface expression of VISTA. This fast adaptation is not only affecting the release of vesicles to the cell surface. Deng et al. (2016) and Liu et al. (2018) also found a rapid endocytosis of surface VISTA. The storage of VISTA in vesicles enables a rapid dynamic adaptation of surface VISTA to any kind of environment.

Thus, my observations were consistent with VISTA being rapidly released to the cell surface in high amounts in response to an immunogenic stimulus, but it might be endocytosed quickly when VISTA is not needed anymore or blocked by an antibody. This dynamic change in surface expression need to be considered for all future expression measurements and dosage calculations of VISTA antibodies. Therefore, detection of VISTA on the cell surface would only mirror a transient situation and underestimate its true expression level.

Effect on nuclear VISTA

While the immunogenic stimulus showed a clear activation and effect on the nuclear expression of VISTA, cell density did not lead to as strong effects. BMDMs only showed a small difference in activation state between different cell densities. Very high cell concentrations showed a slightly increased activation but did not lead to a corresponding higher IL-6 concentration. Very high cell densities led to less nucleus staining. This could be a hint that the results of more nuclear PD-L1 with missing cell-cell contact (Satelli et al. 2016a) could be also true for VISTA. But lower cell densities than normal were not testable due to technical reasons. Also, it is not clear whether increased and decreased cell densities give opposite results.

In general, the differences in nuclear VISTA expression due to cell density were not as strong as observed for PD-L1. For VISTA, the immunogenic stimulus was more important and had higher impact on the nuclear expression than cell density. It would be interesting to check for the impact of immunogenic stimuli on the nuclear PD-L1 expression in the future.

The fact that VISTA RNA levels were increased with the nucleus staining of VISTA and that sustaining LPS stimulation led to a higher VISTA fluorescence in the cell body could be a hint that nuclear VISTA promoted its expression. Nuclear VISTA after immunogenic stimulation could be a mechanism to restore the dropped level of vesicular VISTA after exocytosis. Most proteins in the nucleus have a transcriptional role and many start a positive feedback mechanism. In addition, the missing nucleus staining and increase in RNA level after addition of the inhibitors DAPT and TAPI-2 supported the following model we developed (Figure 5.2.1):

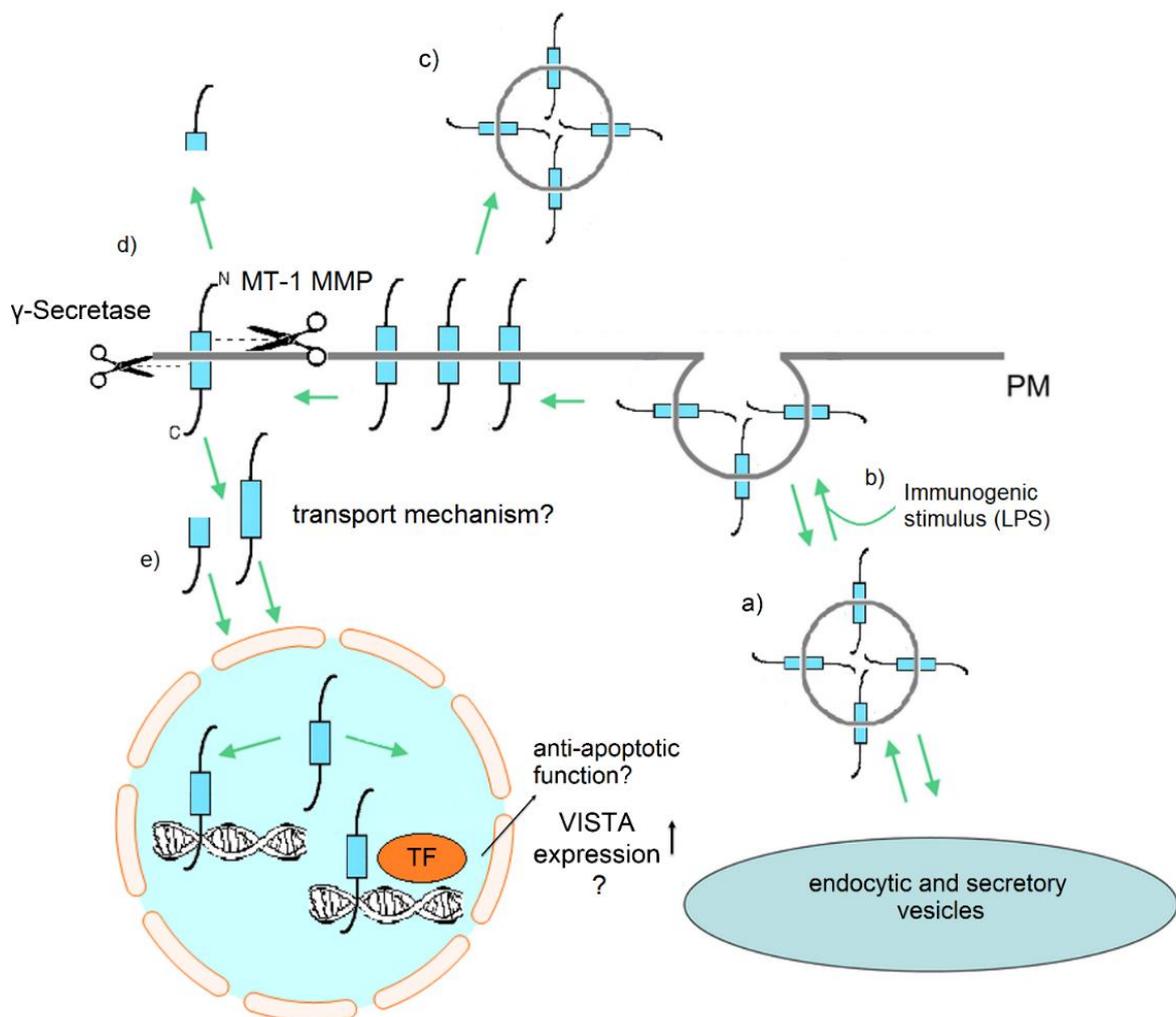

Figure 5.2.1: Model of intracellular trafficking and translocation of VISTA. VISTA is intracellular stored in vesicles (a), which are preferentially released to the plasma membrane due to immunogenic stimuli (b). On the plasma membrane, the secretion of VISTA in exosomes is possible (c) as well as the shedding of the extracellular VISTA domain (d). The intracellular domain or the whole VISTA protein can translocate towards the nucleus (e) maybe utilized by the γ -secretase. In the nucleus VISTA could fulfill an unknown transcriptional role with anti-apoptotic consequences and/or a positive feedback mechanism increasing the VISTA expression.

I summarized my results regarding the intracellular trafficking and translocation based on the chapters 4.1.3 and 4.2 in Figure 5.2.1. The storage of VISTA in vesicles (a) is widely similar to the NCR CTLA-4 (Linsley et al. 1996), which allows a fast reaction to immunogenic stimuli and a fast regulation of the VISTA surface expression. VISTA vesicles can adapt the cell surface expression rapidly via endocytosis and exocytosis with the plasma membrane. Immunogenic stimuli like LPS led to a fast release of endosomal vesicles containing VISTA (b). VISTA will be brought to the surface leading to a more diffuse and weaker staining and less VISTA positive vesicles in the cytoplasm. This displays the fast adaptation of VISTA surface expression via exocytosis and endocytosis towards the cellular environment, which should be considered for further expression measurements and dosage calculations.

VISTA can be also released from the plasma membrane in the medium via exosomes (c). The expression of VISTA in exosomes shows its importance for cell-cell-communication and would point to a messenger role of VISTA. VISTA signaling via exosomes symbolizes a new way of immunosuppressive communication in tumor microenvironment and should be investigated further.

In addition, the extracellular domain of VISTA can be shedded by the MT-1 MMP releasing it into the medium as a soluble signal molecule (d) (Sakr et al. 2010). Because of its tendency to build dimers it will quickly bind to a VISTA receptor, activating the immune inhibitory pathway.

The intracellular domain can probably be cut by the γ -secretase leading to a translocalization of VISTA into the nucleus (e). Another possibility raising from 5.1.3 is that the whole protein is cut and transported into the nucleus via nucleus-transporters. PD-L1 for example also does not contain any classical nucleus import motif, but shows interaction with nuclear import/export proteins in its interactome (Escors et al. 2018). It would be important to search for binding partners in the cytoplasm and nucleus to explore the transport of VISTA into the nucleus. In both possibilities VISTA has an unknown transcriptional function while interacting with the DNA or transcription factors. Regarding the increased RNA levels of VISTA one possibility would be a positive feedback mechanism where VISTA in the nucleus promotes expression of itself. Of course, it could also be a coincidence of nuclear VISTA expression and increasing VISTA RNA levels. Adapted from the anti-apoptotic function of PD-L1 in the nucleus and the high homology of VISTA and PD-L1 one possible transcriptional role of nuclear VISTA could also be an anti-apoptotic function. The nuclear appearance of VISTA should be confirmed by independent alternative experimental approaches in the future.

Important next steps would be the identification of interaction partners of VISTA for nuclear translocation. In addition, it would be interesting to check the levels of the phosphorylated protein kinase Akt in the nucleus while nuclear VISTA expression. The PI3K/Akt pathway seems to be involved in the upregulation of nuclear PD-L1 displayed by increased phosphorylated Akt in the nucleus (Ghebeh et al. 2010; Satelli et al. 2016; Granier et al. 2017). In addition, it is known that the binding of VISTA receptor also has an effect on the phosphorylation of downstream molecules like Akt (Liu et al. 2015). Therefore, to characterize the effects of nuclear VISTA further, it would be important to quantify the effects on Akt phosphorylation. Additionally, we did not check if the

exosome level varies due to stimulation. Stimulation led to an increased release of VISTA vesicles and nuclear VISTA it would be also reasonable if the secretion of exosomes can also be promoted by immunogenic stimuli.

5.3 Consequences of VISTA overexpression on APCs

The main functional effects of VISTA overexpression were an increased differentiation, increased adhesion, increased phagocytosis on macrophage and tumor cell side and less MHC-II expression (chapter 4.1).

VISTA promotes the differentiation of stem cells via the BMP-4 pathway. In addition, the only identified ligand of VISTA so far is VSIG-3 an adhesion protein. It is responsible for homophilic, calcium-independent adhesion (Yang et al. 2017; Wang et al. 2019). It seems to be reasonable that overexpression of VISTA showed increased adhesion and differentiation. Both can also support each other. With increased adhesion, the celllines will more likely differentiate into macrophages and a higher differentiation into macrophages leads to a stronger adhesion.

The increased adhesion could also have an impact on phagocytosis. To perform phagocytosis, target cells first need to attach to the phagocytes. With increased adhesion and cell clustering, more tumor cells will attach to the phagocytes, promoting the phagocytosis.

For phagocytes with VISTA overexpression I saw a higher increase in phagocytosis than for VISTA overexpression on tumor cells. Beside the promoted cell-cell contact the increased differentiation was probably also one aspect. The celllines only differentiated into “macrophage-like” phagocytes. With the increased differentiation due to VISTA overexpression the cells were probably closer to real macrophages with a higher phagocytosis capacity. The aspects adhesion and differentiation definitely had an impact on phagocytosis of VISTA overexpressing phagocytes.

In addition, the phagocytosis of primary macrophages, engulfing tumor cells with VISTA overexpression was also increased. I conclude that VISTA overexpression also increased phagocytosis itself, not only because of increased differentiation. The primary macrophages were fully differentiated independently of VISTA overexpression. These results confirmed the publication by Yoon et al. (2015) where they observed that VISTA knockout (k/o) cells showed less phagocytosis on the macrophage and tumor cell side. My results were the first independent test of these results by performing the experiments the other way around. Instead of using k/o of VISTA, we used VISTA overexpressing cells. The fact that our results were in agreement with each other strengthens the validity.

Surprisingly, we didn't see the expected differences between different macrophage types. We would expect the highest phagocytosis of the M1 macrophages with pro-inflammatory, bactericidal and phagocytic functions (Hesketh et al. 2017). In comparison to that, M2 macrophages have primarily constructive functions with wound healing and tissue repair. They are able to turn off the immune system activation by secretion of IL-10 and TGF- β . That's why tumor-associated macrophages have mainly M2 phenotype and promote the tumor growth (Galdiero et al. 2013). Somehow these

expected differences are not observable in our in vitro system. This issue is already known from former experiments in other groups (personal communication with Experimental Hematology, UMCG).

The Experimental Hematology identified MHC-II as a possible and unknown binding partner of VISTA and my results demonstrated that VISTA overexpression led to less MHC-II surface expression. These findings link how VISTA can be immunoinhibitory but still lead to increased phagocytosis. With more phagocytosis you would expect more antigen presentation and a higher stimulation of the immune system. But if VISTA expression led to less MHC-II expression, there were less complexes available to present antigens. VISTA led to an increased phagocytosis and an increased clearance of tumor cells or pathogens, but less presentation of their antigens toward T-cells. Therefore, the cells and pathogens got cleared but with less stimulation of the immune system. In addition, the GFP pull-out showed that VISTA was able to bind MHC-II as an interaction partner (Experimental Hematology, UMCG). Binding of MHC-II cluster on other cells would block them that the antigens could not be presented to T-cells, inhibiting the T-cell activation.

This would be similar to the immune checkpoint receptor Lymphocyte-Activation Gene-3 (LAG-3). The main binding partner of LAG-3 is MHC-II preventing the binding of MHC-II to CD4 and therefore affecting the proliferation, activation and homeostasis of T-cells negatively, like PD-1 or CTLA-4. The LAG-3 MHC-II interaction is discussed as target for immune therapy for MHC-II positive cancer like melanoma (Hemon et al. 2011). The effect of VISTA on MHC-II can also be observed in VISTA deficient myeloid cells. VISTA deficiency promotes their activation leading to upregulation of costimulatory molecules like CD80, CD40 and MHC-II (Ceeraz et al. 2017). Similar effects are observable by VISTA antibody treatment. The VISTA antibody activates tumor-associated myeloid DCs by upregulation of CD80 and MHC-II (Le Mercier et al. 2014; Wang et al. 2018). This confirms our findings and supports the importance of further investigations on this immunoinhibitory axis.

Another ligand, which was identified by Yeast-two-hybrid screening and proposed by the interaction network modeling via STRING network, is Smad3 (Szklarczyk et al. 2019).

My results did not show any correlation between VISTA overexpression and RNA level of Smad3, only differences between the cell types. That is a hint that Smad3 is not transcriptional target of VISTA and that Smad3 expression is independent from VISTA expression. We did not test if VISTA expression was dependent on Smad3 expression. Of course, they could still be interaction partner with independent expression.

To get more insight about the possible signaling pathways by VISTA I summarized all publications about VISTA regarding possible dependencies (Figure 5.3.1):

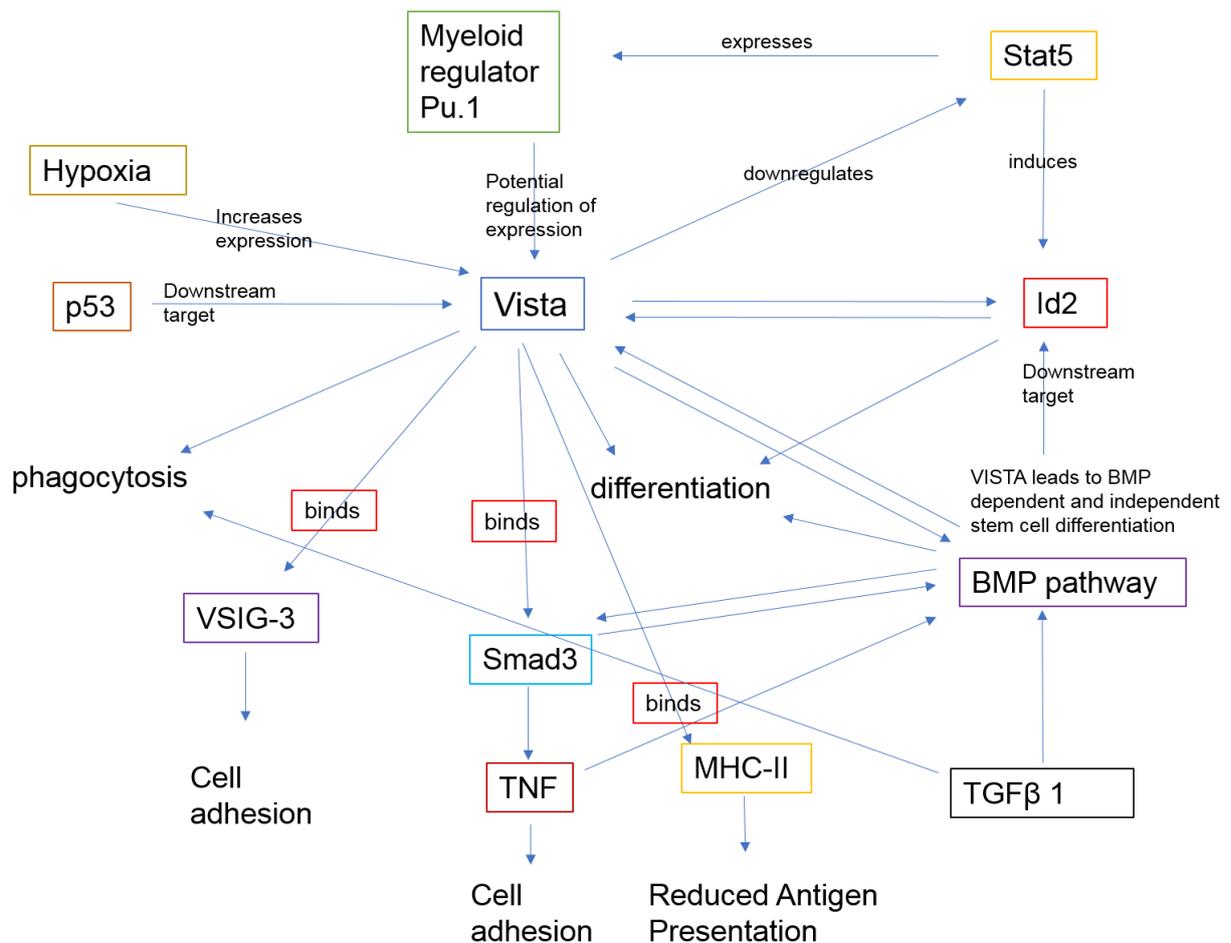

Figure 5.3.1: Overview about all published interaction partners, dependencies and signaling pathways so far. References addressing each pathway are in the main text.

VISTA is a direct transcriptional target of p53, which is similar to PD-1 and PD-L1 that also show increased expression induced by p53 (Yoon et al. 2015). Increased VISTA expression induced by p53 leads to a homophilic interaction of VISTA on macrophages and tumor cells which induces increased phagocytosis and clearance of VISTA-positive tumor cells (Yoon et al. 2015). My results confirmed the increased phagocytosis by VISTA overexpression (chapter 4.3.3 and 4.3.4).

VISTA leads to a BMP pathway dependent and independent stem cell differentiation in embryonic development (Oliveira et al. 2016) which is activated by TGF β -1. My results also confirmed that VISTA promotes differentiation (chapter 4.1.2 and 4.3.1). The transcriptional regulator Id2 is a downstream target of the BMP pathway and follows the VISTA expression in a EMT mouse model where it enhances migration and invasiveness (Coma et al. 2010; Li et al. 2012). Id2 is also higher expressed on more differentiated celllines and macrophages and seem to promote differentiation (Ishiguro et al. 1996). This is supported by my results where PMA differentiation led to higher Id2 levels which increased for THP-1 cells further with VISTA overexpression and a stronger differentiation (chapter 4.3.5). Id2 is induced by Signal Transducer and Activator of Transcription 5 (Stat5) which could be downregulated by VISTA. A VISTA knockout leads to more activated Stat5 (Li et al. 2012). Interestingly, Stat5 regulates

the PI3K/Akt pathway which is impaired after binding of the VISTA receptor on T-cells (Liu et al. 2015).

Stat5 also induces the expression of the transcription factor Pu.1, which activates genes for myeloid cell development (Li et al. 2012). Pu.1 is in addition discussed as a potential regulator of the VISTA expression (Borggrewe et al. 2018) but not proved yet. Also hypoxia seem to promote VISTA expression (Deng et al. 2019). This is also observable for the VISTA homologue PD-L1 which is upregulated by HIF- α in the hypoxic tumor microenvironment (TME) (Noman et al. 2014).

The three confirmed or proposed binding partner of VISTA are VSIG-3, Smad3 and MHC-II. VSIG-3 and Smad3 are responsible for the adhesion of cells displaying the important impact of VISTA on adhesion. My results confirmed an increased adhesion with higher VISTA expression (chapter 4.3.1, 4.3.2 and 4.3.3). In addition, (Sakr et al. 2010) also found enhanced adhesion to fibronectin due to VISTA.

The binding of MHC-II (chapter 4.3.5) led to less antigen presentation, which is highly similar to the immune checkpoint receptor LAG-3 as already explained.

In summary we can conclude that our results provided new and supporting properties of VISTA which complement the interaction network of VISTA. With more insight on the interaction partners and signaling pathways of VISTA, a sufficient characterization of VISTA for future therapy is possible.

5.4 Future perspectives

We can conclude that VISTA has a much more complex function than described so far. Former publications described VISTA either as a differentiation protein or a classical negative checkpoint regulator with additional expression on Antigen Presenting Cells (APCs). My results showed that VISTA is affecting adhesion, differentiation, phagocytosis and the immune function of APCs. In addition, VISTA is not exclusively expressed on the plasma membrane as described so far. It has a unique expression pattern with storage in vesicles, translocalization to the nucleus with unknown transcriptional function and is a signal molecule as shedded IgV-VISTA molecule in the medium as well as in exosomes. All these results display its important role on APCs which is investigated poorly yet. But the new characteristics discovered in this thesis, revealed unexpected similarities to other immune checkpoint molecules which complete the properties of VISTA published so far.

For the future therapy approach it is important to further investigate the VISTA expression on more tumor types. In addition, the VSIG-3 expression should be investigated to consider an immune therapy against the VISTA-VSIG-3 axis. VSIG-3 is upregulated in intestinal gastric cancer, colorectal cancer and hepatocellular carcinoma, displaying promising new targets for immunotherapy of this axis (Marin-Acevedo et al. 2018; Wang et al. 2019).

The second promising approach revealed in this thesis is the VISTA-MHC-II interaction. Interesting questions for further research would be: Is VISTA responsible for decreased antigen presentation? Can the VISTA-MHC-II interaction be prevented

by an anti-VISTA antibody? Are MHC-II positive tumors like melanoma promising targets for immunotherapy against the VISTA-MHC-II axis?

One additional aspect of VISTA binding MHC-II could be the possibility of overcoming resistance of PD-1 therapy. One possible resistance mechanism against PD-1 therapy is the downregulation of HLA-associated antigen presentation (Dempke et al. 2017; Kakavand et al. 2017). Human leukocyte antigen gene complexes (HLAs) encode the MHC classes I and II. If the blocking of VISTA prevents the downregulation of MHC-II mediated antigen presentation, the combinatorial therapy of VISTA and PD-1 would be able to overcome this resistance.

To use VISTA as a safe and efficient therapy in the future, it is important to further investigate its role on all immune cells, to identify the signaling pathways VISTA activates and its interaction partners. For dosage calculation, the storage of VISTA in vesicles should be considered as well as its adapted expression pattern towards immunogenic stimuli. To understand the function of VISTA, its transcriptional role should also be investigated before applying VISTA therapy on patients. In addition, the amounts of shedded VISTA IgV domain and the release of VISTA in exosomes need to be investigated in the tumor microenvironment. These extracellular VISTA signals display a new dimension of communication via VISTA in the tumor microenvironment which need to be considered for a VISTA therapy in the future.

The results of this thesis support the approach of VISTA being a promising new target for immune therapy against cancer. Especially in combination with PD-1 or PD-L1, VISTA could be able to solve some of the occurring resistance and response rate issues.

Curriculum vitae

Lena Dübbel

Date of birth: 24.04.1992 in Oldenburg (Oldb)
Email: lena.duebbel@uni-oldenburg.de

Education and Qualification

- 12/2016 – 12/2019 **PhD student (Dr. rer. nat.)**
Carl von Ossietzky University of Oldenburg
- Thesis: Characterization of signaling pathways in tumor immunology and immune therapy (Prof. Dr. Karl-Wilhelm Koch, Biochemistry)
- Research stays in the Experimental Hematology at the UMCG in Groningen, Netherlands in total for 5 month to transfer my results to the human cell system
 - 3-month supervision of an American participant of the DAAD Rise program
 - Focus: cell culture, immunohistochemistry, purification and characterization of proteins
- 10/ 2014 – 11/2016 **Master of Science, Molecular Biotechnology**
Technical University of Munich, Thematic priority on cells and medicine
- Thesis: Analysis of nutrient dependency and molecular characterization of metabolic requirements for antigen uptake, processing and MHC-I-restricted cross-presentation for CD8 T cells through liver sinusoidal endothelial cells compared to dendritic cells (Univ.-Prof. Dr. med. Percy Knolle, Molecular Immunology and Experimental Oncology)
- Research internship over six weeks at the institute „Molecular immunology and Experimental Oncology “ of Prof. Dr. Knolle at University hospital “Klinikum rechts der Isar” about immune function of LSECs
 - Research internship over eight weeks at „Microbial diversity“ chair in the group of Dr. Neuhaus about overlapping genes in EHEC *sakai*
- 10/ 2011 - 07/ 2014 **Bachelor of Science, Molecular Biotechnology**
Technical University of Munich
- Thesis: Investigation of the soluble expression of the CMP-N-acetylneuraminase synthetase of *Neisseria meningitidis* with masked membrane anchor (Prof. Dr.-Ing. Dirk Weuster Botz, bioprocess engineering)
- 07/2011 **Abitur**
Herbartgymnasium (Oldenburg)

Professional Experience

10/2017 – 12/2017	Lecturer for Biochemistry of the Cell Seminar, at Biochemistry Group, Prof. Koch, Carl von Ossietzky University of Oldenburg
04/ 2013 – 07/2013	Student Employee at Chair of Biochemistry, Prof. Dr. Skerra, Technical University of Munich
2010	Honorary group leader of a youth group in the OTB-tent camp Selker Noor (training course „KTS & JuLeiCa Ausbildung“ for trainer assistant)

Courses within the PhD program Neurosensory Science and Systems

- Engagement as member of the Organization-Team of the research training group “Molecular basis of sensory biology”, organization of an international conference
- Good Scientific Practice (GSP) – Basistraining certificate
- Good Manufacturing Practice (GMP) – Basistraining certificate
- Qualitätssicherung in der regulierten Forschung – GxP (GLP, GMP, GCLP) – Karlsruher Institut für Technologie (KIT)
- Project Management – Fisher&Friends certificate
- Selfmanagement and Selfpresentation
- Mentoring program 2018-2019 for female young researcher
- How to publish in peer-reviewed journals – Tress and Tress certificate
- Scientific Image Processing and Analysis – Biovoxxel certificate
- Advanced Presentation techniques

Further Skills

Laboratory skills	Cloning, expression and purification of recombinant proteins Isolation and differentiation of several cell types from mice and human Immunohistochemistry, FACS, Western Blot, SDS-PAGE, Elisa, phagocytosis assay, migration assay, Ca-binding Assay with radioactive isotopes	
IT skills	Microsoft Office, ImageJ, Sigma Plot, GraphPad Prism, Flow Jo	
Language	German	Native
	English	fluent, C1 Level
	French	Basic

List of publications

Articles

Submitted: "Co-regulation of metabolism and immune functions in murine liver sinusoidal endothelial cells"; Kerstin Lohr, Sainitin Donakonda, Michael Dudek, Tobias Baumann, Max Lüdemann, Silke Hegenbarth, Lena Dübbel, Carola Eberhagen, Savvoula Michailidou, Marco Prinz, Bastian Popper, Hans Zischka, Percy A. Knolle; Science Reports 2019

In preparation: "Intracellular localization of the negative checkpoint regulator VISTA in immune cells"; Lena Dübbel, Karl-Wilhelm Koch, Edwin Bremer

Poster presentations

Dübbel, L., Meyer, H.N., Koch, K.-W. (2018); „Intracellular localization of the negative checkpoint regulator VISTA in Antigen Presenting Cells"; 5th European Congress of Immunology, Amsterdam, Netherlands

Dübbel, L., Meyer, H.N., Koch, K.-W. (2017); „VISTA, a new potential target for tumor immune therapy"; Joint Networking day- The Groningen-Oldenburg Symposium, Groningen, Netherlands

Oral presentations

Intracellular localization of VISTA, a new target for cancer immunotherapy (2018), Sensory Systems in Health and Disease, Verona, Italy

Danksagung

Hiermit möchte ich mich gerne bei allen Personen bedanken, die mich während meiner Promotion begleitet und unterstützt haben. Dankeschön, ohne euch wäre die Arbeit nicht annähernd so schön und erfolgreich abgelaufen!

Als Erstes geht ein großes Dankeschön an Prof. Dr. Karl-Wilhelm Koch! Danke für die ungeplante Übernahme und Betreuung meiner Doktorarbeit. Danke für die Unterstützung, Betreuung und Hilfestellung während meiner Arbeit und vielen Dank, dass du meinewegen einen Ausflug in die Tumorummunologie gemacht hast!

In addition I want to thank Prof. Dr. Edwin Bremer being my second referee. Thank you for your invitation, all the constructive discussions, your patience with me and the possibility to hospitate in your laboratory!

Des Weiteren möchte ich mich bei apl. Prof. Dr. Ulrike Janssen-Bienhold bedanken. Danke, dass du mich bei allen Mikroskopfragen beraten hast, dich für mich eingesetzt hast und mir immer mit Rat und Tat zur Seite standest.

Ich möchte mich auch bei Tanja Seifert und Scott Wu für ihren Fleiß und ihre Arbeit am VISTA Projekt mit mir, bedanken.

Vielen Dank auch an Bo der sehr viele Stunden und Nerven in den Versuch investiert hat, um meine prozentualen Daten statistisch auswertbar zu machen.

Ganz besonders möchte ich mich auch bei der Arbeitsgruppe Biochemie bedanken. Danke für die herzliche Aufnahme, die Unterstützung und die nette Atmosphäre. Ich vermisse unsere Kohlfahrten, Weihnachtsfeiern und Betriebsausflüge jetzt schon! Danke an Werner, Charlotte, Seher, Hanna und Chad für eine großartige Bürogemeinschaft! Danke für die vielen schönen Gespräche, die gute Musik, die hilfreichen Ratschläge und die konstruktiven Diskussionen. Danke an Jutta für die Hilfe in der Zellkultur und dein offenes Ohr für mich.

Danke auch an Dana, Nicole, Katharina und Haijia. Die Arbeit mit euch hat mir sehr viel Spaß gemacht und ich hoffe ich werde weiterhin zu den Cocktailabenden eingeladen. Danke auch an Laura und Kristina für die vielen schönen Gespräche, euer offenes Ohr und sehr lustige Zeiten als Zimmergenossinnen.

Einen besonderen Dank auch an Michael, der mich geduldig während dieser stressigen Zeit ertragen und unterstützt hat.

Abschließend möchte ich mich ganz herzlich bei meiner Familie bedanken, die mich seit Jahren aufbaut, auffängt, unterstützt und anfeuert. Ohne eure Hilfe und Motivation wäre ich nicht in der Situation, in der ich jetzt bin. Danke!

Erklärung

Hiermit erkläre ich, dass ich die vorliegende Arbeit selbstständig verfasst habe und keine als die angegebenen Quellen und Hilfsmittel verwendet habe. Ich versichere, dass diese Arbeit weder in ihrer Gesamtheit noch in Teilen einer anderen Hochschule zur Begutachtung in einem Promotionsverfahren vorliegt oder vorgelegen hat und dass ich die Leitlinien guter wissenschaftlicher Praxis der Carl von Ossietzky Universität Oldenburg befolgt habe. Weiterhin versichere ich, dass im Zusammenhang mit dem Promotionsvorhaben keine kommerziellen Vermittlungs- oder Beratungsdienste (Promotionsberatung) in Anspruch genommen worden sind.

(Ort, Datum)

(Lena Dübbel)
